LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF THE SKIN (*concluded.*)—
Warts, Corns.

DISEASES OF THE CELLULAR TISSUE.—
Furuncle Anthrax.—Tumors.—Lipoma, Encysted Hydatid, Sarcomatous, Fibro-Nervous? Their Causes, Symptoms, Nature, and Treatment.

DISEASES AND INJURIES OF ARTERIES.—
General Remarks.

CORNS.

CORNS are a circumscribed thickening of the epidermis of the toes. They are observed at the dorsal surface, at the more prominent joints, between two toes, at the external, rarely at the internal, border of the foot—generally at all points subjected to pressure. They are almost always flattened, inserted, as it were, into the skin, are gradually formed, and do not attract attention until they have acquired a certain volume, when they occasion lancinating pungent pain, as if a nail were driven into the part. Sometimes they commence by being acute, especially in persons with delicate skin. The pain is then acute, and, if cut into, a serous fluid escapes, the suffering diminishes until they acquire the ordinary characters of corns. Pathological anatomy shews us, when we cut or extirpate a corn, the skin sensibly depressed. If we macerate the toe of a dead person which has a large corn upon it, after a short time it is easily removed; the centre of it enjoys considerable tenacity, and, at the point which cor-

responds to the centre, the chorion is depressed, or even perforated. Corns are inorganic, simply formed of thickened cuticle: this thickening is produced by a vice of secretion, and this vice of secretion is produced by pressure exercised by ill-fitted shoes. This pressure prevents their outward extension, so that they compress the chorion and subjacent nerves, cause acute pain, and may, at last, thin, and perforate the chorion. A first means of cure is to wear easy shoes. The acute pain may be moderated by cutting away the exuberant part with a sharp knife. The central point or eye may be very often removed after soaking the foot in warm water. Plasters of many kinds will be found useful in treating corns, provided the patient, at the same time, reform his shoes. It is well to relieve the central nucleus from pressure: this may be done by applying upon the part a piece of doe-leather spread with adhesive plaister, with a hole cut in the centre large enough for the corn to press through, cutting, from week to week, the prominent part. They may be destroyed by caustics—nitrate of silver, caustic potash, nitric acid, &c.; but, in inexperienced hands, this class of remedies may be found hurtful.

WARTS.

Warts are not always, like corns, a simple epidermic secretion. The chorion and the rete mucosum appear simultaneously affected. When we cut vertically a large wart, the cuticle is seen progressively to increase in thickness up to the centre of the wart; the chorion is thickened like the epidermis, and sends into its thickness prolongations, which are called roots. In cutting into a great many warts, we always see in their substance blackish points. In superficial warts the corpus mucosum seems alone to be affected. Pressure is not always the cause of warts. It is said that the blood which they sur-

nish has a contagious property. I know a person who has on his hand a chain of warts, which he says are developed exactly on the line of a streak of blood shed in cutting another wart. They occur at all ages, but they are certainly most frequently seen in childhood and youth; and especially in those who handle irritating substances, or have little regard to cleanliness. Some persons appear to have a kind of predisposition to them, and they return after they have been destroyed, in spite of every regard to cleanliness. Warts often disappear spontaneously—are easily removed or destroyed; but in either case are apt to be re-produced. They may be tied with a silk thread or horse-hair; if their base be broad, they may be removed with a knife or curved scissors, or may be destroyed by caustic. When they are excised, they ought first to be bathed for half an hour in warm soapy water; they must then be removed by thin layers until they begin to bleed, when the surface should be rubbed over with lunar caustic. When nitric acid is employed, the surrounding parts must be protected by adhesive plaister. A strong solution of the muriate of ammonia applied upon them twice a day will usually get rid of them. Certain acrid vegetable juices will also effect the object. The credulous believe that they can be “charmed” away. The charmers may be divided into classes: one uses mystical words, and cure without touching them; those are inoffensive: another employ the juice of certain acrid herbs; this class may do mischief. The pretended cures depend, not upon the means used, but upon the time they are used. Warts tend to cure spontaneously towards the age of puberty.

DISEASES OF THE CELLULAR TISSUE.

Furunculous inflammation, though it unquestionably affects the skin to a certain extent, yet may more properly be classed with the diseases of the cellular tissue.

The cells of the chorion are penetrated at all points by small conical prolongations, derived from the subcutaneous cellular membrane: inflammation of these prolongations gives rise to *furunculus* or *boil*; the simultaneous and confluent inflammation of several of these appendices constitutes *anthrax*. When these cones are so affected, the cutis resists their development, and a species of strangulation and mortification takes place. Left to themselves, these affections always terminate in the mortification and expulsion of one or more of these small cones. *Furuncular inflammation* is commonly connected with a disordered condition of the stomach and bowels, and is scarcely ever the effect of mere inflammations of the skin.

A *boil* is, therefore, an inflammatory swelling of the cellular substance and the skin—is circumscribed, conical, and prominent; hard, very red, hot, and painful, and terminates in the formation of a very small quantity of matter, and the expulsion of a mass of mortified cellular tissue. The buttocks, the thighs, the back, the axilla, the neck, and the parietes of the abdomen, are the regions of the body for which they seem to manifest a preference. Usually a boil is not seen alone; it has others near it. Strictly speaking the inflammation of a single cone constitutes a boil; but at certain seasons, and in many cases as a consequence of bad or insufficient food, a larger tumor is developed, but without the constitutional symptoms of anthrax. Last year I had, at the same time, two patients; one, a woman of 22, living in London; the other, an Irish woman, a hay-maker, aged 40, with this species of tumor in the supra clavicular fossa. These tumors have been named by some pathologists *furunculus anthracoides*.

A boil begins by a small hard conical tumor, of a bright or violet red colour, which, in a few days, principally by irritating the surrounding tissue, may acquire the size of a large nut, or walnut. The pain is sometimes very acute; compared, by some, to the pain which would be produced by a drill or gimblet. From the fourth to the eighth day it rises to a point; the apex becomes white, softens, and finally gives way, when a small quantity of sanguinolent pus escapes by an opening as small as if it had been made with a fine probe, and the subjacent slough is exposed; when this is expelled the tumor seems to be pierced by an open-mouthed cylindrical cavity. The pain now ceases, the skin collapses, the cavity fills up, and, by the end of a fortnight, no other trace is left than a small depressed cicatrix of a dusky red colour.

Furunculi are never dangerous of themselves; but their situation sometimes renders them very troublesome. I recollect a case in which one was developed in the perineum between the anus and scrotum, which rendered the excretion of urine very difficult, and simulated a urinary abscess.

Treatment.—It is stated, in books, that we may prevent the development of a boil by applying a leech directly upon the little tumor, or by applying caustic potash, or lunar caustic, upon it: I have never succeeded with either of these means. Warm fomentations will usually afford relief; if, however, the pain be severe, the simple division of the integument affords the most efficacious relief. As a topical application a simple poultice is probably the best. But in these cases, the cause being usually internal, and continuing to act, successive

crops appear, and emetic or purgative medicines are exhibited to arrest them. Fosbroke advised that diluted sulphuric acid should be largely administered as a very effectual means of lessening pain and preventing successive eruption: I have never derived much advantage from this treatment: but I constantly experience the most signal good effects from the exhibition of the liquor potassæ in infusion of gentian—half dram doses three times a day.

ANTHRAX OR CARBUNCLE.

Between furunculus and anthrax, the only anatomical distinction which can be drawn is, that the former affection is confined to one, two, or three cellular cones; the latter to many. Anthrax is usually seen alone: furunculi are often numerous. Furunculus is seen at all ages. Anthrax is rarely seen in children—is much more frequent in the adult, and in those broken down by age, misery, infirmities, or by good living.

The term anthrax has been applied to two very different diseases; the one, possessing many characters in common with furunculus, differing from it only in volume; the other, *malignant* in its nature, belongs to that class of gangrenous diseases produced by miasma, or septic virus.

Furunculous Anthrax, which alone we shall consider here, is an inflammatory tumor, circumscribed, very hard, very painful, of a dark red colour, and accompanied by burning heat. This tumor is constantly terminated by the mortification of the cellular tissue which it affects, and by the destruction of a portion of the skin by which it is covered. Women and children are much more rarely the subjects of this disease than adults and old men.

It is commonly developed in those situations where there is an abundance of cellular tissue—the nape of the neck, between the shoulders, the lumbar region, the parietes of the thorax, the abdomen, and the thighs. It is occasionally seen in the inferior maxillary region, and in the supra-clavicular spaces.

Causes.—We are not at present cognizant of the causes of this disease: in some cases it would seem to be a consequence of bad or indigestible food; in others, of the application of acrid or irritating substances to the skin, of punctures, or habitual filth; but then it also attacks persons who are the most attentive to cleanliness. It is certainly more frequently seen in spring and autumn than in summer and winter: this would seem to prove that damp, cold, and vicissitudes of temperature, are favourable for its production. It not unfrequently succeeds to measles and small-pox in adults. It is very generally believed

that anthrax is connected with certain deranged functions of the stomach, the liver, and the uterus; and this appears reasonable when we consider how often anthrax seems to be caused by improper food, how often it is presented in the character of a critical affection in persons suffering from bilious or nauseous fevers, and how commonly it is observed in women at the period when the menstrual function ceases, as compared with any other epoch of life.

Symptoms.—The occurrence of anthrax is often preceded by boils; indeed, during its development, we often see the point surrounded by boils. Sometimes it appears without any material constitutional disturbance: at other times it is preceded by anorexia, lassitude, rigors, and other symptoms which denote digestive derangement. At first there is little projection beyond the surface; and commonly its extent is not great. Sometimes during the first few days a flat vesicle is seen, filled with a reddish sanious fluid, as in malignant pustule. Usually its progress is rapid; and in eight or ten days it may attain a surface equal in extent to the palm of the hand: indeed, on the back, the thorax, and the abdomen, they have sometimes been seen nine or ten inches in diameter. As the tumor enlarges, it projects so as occasionally to pass the level of the skin by several inches. Anthrax continues very hard up to the moment when mortification seizes upon that part of the cellular tissue which occupies the most projecting part; and even when that portion is softened the surrounding part continues hard, and the base enlarges. The skin covering the tumor is of a violet red colour, which does not disappear upon pressure; and around its base the redness is erysipelatous: this indicates the ulterior progress of the disease. The heat is acrid and burning, especially at the summit of the tumor; and it does not diminish until an opening is made. The pain is very acute, but varies at different points of the tumor; sometimes it is heavy, dull, tensile; at others, lancinating, and the patients complain of the lancinations extending to a considerable distance; sometimes it is a gnawing sensation, as if it were torn with teeth. Whenever the tumor is large, or affects irritable subjects, there is fever, restlessness, sleeplessness, the skin is hot, the urine dark and in small quantity, and the head painful.

Other symptoms may exist connected with the situation or size of the tumor. Thus when it occupies the lateral or anterior part of the neck, respiration and deglutition may be impeded, a sensation of heat is complained of in the larynx and trachea, and there may be a troublesome

cough; the face is puffy, and the head painful, from the jugular vein being interfered with. If the tumor be seated on the thoracic parietes, respiration is embarrassed, and the inflammation may be extended to the pleura. If it be seated in the abdominal parietes, still it affects respiration, and the pain is much increased by efforts in going to stool; or, indeed, there may be vomiting, and even peritonitis. Left to itself, it softens at the summit, the skin is dark violet or bluish, and if the finger be applied upon the point we become sensible of an obscure fluctuation. After some days the skin ulcerates from within outwards, and a small quantity of sanguinolent pus, together with some shreds of sloughy cellular tissue, escapes; the opening enlarges, and a small quantity of thick pus continues to flow out. Even after this you will often observe that the anthrax continues to increase in extent and depth; and then the relief which the patient experiences from the opening is small. The softening goes on, and many irregular openings are formed; they enlarge and unite. Destruction is not limited to the skin and cellular tissue; small arteries and veins are ulcerated, and blood in small quantity often escapes; but I know no case where any considerable hæmorrhage has occurred. When the skin is largely perforated, we see distinctly the sloughing cellular tissue. It exhales a fetid smell, not, however, like that yielded by substances in a state of putrefaction; nor does it assume that dark colour which is seen in other kinds of gangrene. By little and little the cellular sloughs are thrown off, suppuration becomes more abundant, and the pus is thinner; pain, heat, fever, and tension diminish. When the sloughs are thrown off, the naked aponeurosis is often seen; it is perforated, and the pus is seen to escape by the openings which it presents. The skin corresponding to the circumference of the tumor is raised, thin, bluish, and so disorganized as to be incapable of again uniting to the subjacent tissue. The disorganized tissues are gradually thrown off, and the fundus of the ulcer is covered with granulations; the edges are softened, and the work of cicatrization proceeds. The cicatrix is always irregular and puckered, and for a long time retains a brownish red colour. If the anthrax have been very large, the cicatrix may tend to constrain certain movements; but this may usually be prevented by moderate care.

Anthrax, such as I have described, benign in its character, is sometimes a fatal disease; it may destroy life when very large—when seated in the walls of a splanchnic cavity, the inflammation being communicated to the serous surface. In

aged persons, or in those broken down by other diseases, it may also be fatal. Ordinarily, however, when not very large, and occurring in persons of good constitution, the disease is not dangerous.

Dupuytren was accustomed to divide the progress of anthrax into four periods—that of *invasion*, of *suppuration*, of “*deterision*,” and of *cicatrization*. The first, characterised by loss of appetite, thirst, whitish or yellowish coating on the tongue, with or without redness of the edges; sometimes epigastric tenderness, heat of skin, acceleration of pulse, and other signs of gastric irritation. In some cases the tumor appears without these precursory symptoms. It is circumscribed, tense, red, livid, or glistening, accompanied by burning heat. The inflammation proceeds for eight or ten days, and, when it has acquired a certain degree of intensity, reacts on internal organs, whence results exasperation of the gastric symptoms, or their manifestation, if they are not already developed. The *second period* extends from the tenth to about the twentieth day. In this the suppurative action is established, and the cellular and fibrous tissues are inflamed and gangrenous. The integument is perforated from within outwards by many very small openings, each corresponding to the apex of a cellular cone; through these small openings a purulent fluid escapes. Soon these openings enlarge by coalescing, and ultimately they are confounded in one—in a single opening. We then see the slough, resulting from the mortification of the cellular tissue, impregnated with pus, and yielding a fetid odour. Towards the end of this period, the pain, the general heat, the quickened pulse, and the thirst diminish. The *third period* extends from the third to the fourth week; the suppuration becomes more and more abundant, the slough is detached, and a large wound is presented. The skin forming the edges of the ulcer is livid, bluish, and sometimes so thinned as not to be susceptible of adhering to the subjacent parts. The *fourth period* has no fixed duration; it depends on the extent of the loss of substance of the skin. When the edges are much thinned, cicatrization is long in taking place.

Treatment.—When anthrax is produced by external causes, is not preceded by derangement of functions, and is not large, no inconvenience will be felt by attempting its resolution by means of a good number of leeches applied to its surface, or even by the application of cupping glasses. Sometimes relief may be obtained by the application of cold; and the progress of the disease may be arrested. If, however, the disease proceed from constitutional causes, it may not be wise to employ the

latter means, as it may suddenly induce gangrene. Emollient cataplasms are often very fatiguing to the patient, and are, in my opinion, useless, except as relaxing agents: warm water would, therefore, do better. Plasters, ointments, and greasy applications, increase the burning heat. If we bear in mind that anthrax is essentially an inflammatory disease, that it only terminates in gangrene because the cellular tissue is strangulated, we shall have distinct ideas of the practice which should be followed: it was in consonance with this principle that Lallemand made a circular incision which relieved the strangulation and emptied the capillaries; but this circular incision will not do when the tumor is large, or situated in the vicinity of large vessels and nerves. The crucial incision is much more advantageous; but to attain the end, the incision must be deep, and extend beyond the circumference of the tumor. When the tumor is very large, it may be necessary to make more incisions. Soon the suppuration becomes considerable, and the poultice should be removed three times a day. We must not extract with violence the sloughs, or we may produce much pain and some hæmorrhage; but, when hanging about, we may cut them off with a scissors. If suppuration be slow, it may be necessary to stimulate with resinous or balsamic substances. If the digestive system be much deranged, we may at first give an emetic and laxatives; during the period of acute inflammation, the patient should be carefully dieted. If pain be violent, and no congestion or constipation, we may give opium. When suppuration is established, and fever has ceased, we must sustain the patient by diet and tonics.

TUMORS.

Lipoma.—Among the tumors developed in the cellular tissue are some formed almost exclusively of adipose matter—*lipoma*. These tumors are slowly developed, and usually without attracting attention; they present to the touch a peculiar softness, which may be compared to that of eared cotton; their surface is irregular, presents knobs which are not hard, and which are easily depressed. When they attain a certain degree of development, their increase is often rapid, and their bulk may become enormous. So long as the tumor is small, the skin over it suffers no change; but when it is large the skin acquires a tension proportioned to its volume, the circulation is interfered with, the cutaneous veins are distended, the skin inflames, especially when it is seated on a point where it is exposed to friction or external violence. But lipoma may be seated also in the adipose tissue; in this latter case they are

sometimes formed of irregular masses of fatty matter in certain regions, and present no well-defined limits. In this case the borders of the tumor are insensibly confounded with surrounding parts (*lipoma diffusum*); it is remarkably soft, is easily compressed, and is so adherent to the skin, that this latter presents scarcely any mobility, and does not present a complete cyst. The adipose matter which it contains is similar in all respects to that of the rest of the body, except that it is a little firmer. That kind which exists between the layers of the cellular tissue is more deep seated, is generally covered with a layer of adipose matter, is perfectly circumscribed, very moveable, and elastic; and it is surrounded by a particular cyst. Usually the parietes of the cyst are thin; in rare cases they are fibrous, or even cartilaginous.

In general we do not know the causes of lipoma; they now and then succeed to pressure, to a blow, or other violence; they are met with at all ages, in both sexes, most frequent, however, in adult life and in the female; and their most common seat is the neck, the shoulders, or the back. It is not uncommon to see many of these tumors upon the same persons.

Treatment.—These tumors constitute a disease of importance, inasmuch as in some cases they are developed very rapidly. When small, they sometimes seem to yield to counter-irritation; yet, as a rule, ablation is the only treatment which promises a speedy cure. The operation is simple and easy when the base of the tumor is not very wide, but it may offer difficulties, and sometimes danger, when the tumor is very large, when it is in the vicinity of important organs, and when its prolongations extend far and wide. In such cases it is sometimes impossible to remove the whole of the morbid growth, and then the disease is reproduced. The extirpation of these tumors should be done in conformity to certain rules; it should be done with a bistoury; the incision should extend beyond the margin of the tumor, and the tumor should be dissected out with the cyst; the lips of the wound should then be fairly brought together, and union by first intention proceed. If the tumor be very large we shall sometimes fail in this; but we oftener fail from leaving some portion of the cyst behind.

ENCYSTED TUMORS.

Under this denomination we include *tumores cystici*, *saccati tunicati*, *cystides*, *lupia*, &c., which are developed in the subcutaneous or interstitial cellular tissue. They are characterised by a proper cyst, in the cavity of which a particular secretion is made. Bichat demonstrated almost to evi-

dence, that this cyst, instead of being formed, as was previously supposed, by the thickening and distention of an arcola of cellular tissue, was constituted by a true new product, which, in its nature and vital properties, should be assimilated with serous membrane. The consistency and the nature of the matter accumulated within these cysts have caused their division into three varieties: serous (cystis serosa, hygroma); *melictric*, in which the matter contained presents the consistency of honey; *atheromatous*, in which the matter resembles pap or panada.

The nature of the cyst is very various: often they are hard, compact, fibrous; sometimes horny, or even osseous. The internal surface is frequently smooth, shining, sometimes villous; it may even present hairs at its surface. In some the organization resembles that of a mucous surface; sometimes it is reticular. The adhesion of the cyst to surrounding tissues is not usually very intimate. At first they are always very small, and slowly developed; usually round, and their limits well marked; but their form may be influenced by surrounding organs. The sensation derived from pressure varies with their contents: sometimes tense, elastic; sometimes fluctuating; sometimes solid and resisting, the skin covering them being unchanged. Often, after acquiring a certain bulk, they remain nearly stationary through life. Sometimes, without apparent cause, or in consequence of external violence, they may inflame, and the nature of the contents may then change, may become puriform; the skin reddens, ulcerates, the cyst is opened, and the contents are poured out. When this inflammation is violent, the tissue forming the cyst may undergo great changes—may become granular, and be cured; but, instead of this, it may remain fistulous—may end in the development of fungous, or fibrinous, or albuminous matter within the cyst, and resist every kind of treatment.

Another kind of tumor is particularly manifested under the scalp, under the integuments of the face, and the back. They appear to result from the obstruction of one or several sebaceous follicles, whose cavity becomes greatly enlarged. Their form is generally round, and sometimes they give a sensation of fluctuation. They contain a substance which is not very unlike cooked white of egg. They are usually adherent to the skin, and are sometimes filled with hair. The structure of these cysts is variable: in the face they are usually thin; thicker on the back; but most resistant on the head; and, usually, the cyst is as much thicker as the tumor has existed longer.

Treatment.—Many means have been employed to cure encysted tumors; the choice should depend upon the seat and volume of the tumor, its mobility, structure of the cyst, and the sensibility of the patient. Those various means are directed to resolve the tumor—to remove it completely or partially with the bistoury—to destroy it by the ligature—to incise, and destroy the cyst by suppuration. In some cases, more than one of these means are combined.

To obtain the resolution of these tumors, frictions, with irritating fluids, blisters, caustics, and other similar means, have been used. In serous tumors, these means will often succeed in causing the absorption of the fluid; but the lining membrane remains, and in most cases the fluid is again secreted. To dissipate this tendency the means must be continued long, blisters must be again and again applied. Sir B. Brodie, in such cases, is accustomed to use, with decided success, a stimulant and evaporating lotion, composed of *sp. camphorat. sp. tenuior aa. ℥iii.; ss. liquor plumbi diacet. ℥i.* This is kept constantly applied for weeks, and even months. In some cases no sensible effects are observed, other than a redness of the skin, for weeks; but still it must be persevered with.

Extirpation with a bistoury is in many cases the best mode of treatment, when the position of the tumor admits of its removal without much risk of injury to important organs. We must take care to so manage the tumor as to allow of the lips of the incision being brought properly together. Whenever the skin covering is diseased—when the tumor is very large—two elliptical incisions should be made, so as to leave only the necessary quantity to admit of immediate union.

The *ligature* has been recommended, where many and large vessels communicate with it, and when the danger of hæmorrhage may give fair cause for apprehension, or when a cutting instrument may endanger important organs. The constriction is augmented from day to day until the strangulation is complete. I have never seen this mode of treatment employed. It is always long, causes acute pain, and, when the tumor begins to slough, the odour is sometimes intolerable.

The cyst *may be opened*, or it may be destroyed in various ways. When the adhesion of the cyst to neighbouring parts is not intimate, a longitudinal or crucial incision may be sufficient to empty it, when it may be stuffed with lint until suppuration comes on. We may open the tumor with a lancet or caustic; and, for many days in succession, irritate its internal surface, by introducing foreign bodies, or touching the surface with caustic. By little and little

the cyst is detached, and brought away by supuration.

Some persons pass through its greatest diameter a *seton*, which is daily dressed with some irritating ointment until supuration has destroyed the cyst. Others have punctured it with a trochar; squeezed out the contents through the canula; thrown in an irritating fluid, which was retained until the tumor became tense and painful. Emollient applications are then made, and, when fluctuation is perceived, the tumor is opened, and the pus and cyst come away.

Of these several means I prefer opening by incision, and stuffing the cyst with lint; or to open with a lancet, and apply irritating substances to the interior, when the tumor is on the face or neck, because the cicatrix is smaller than after extirpation. Occasionally, after discharging the contents of these tumors, we can seize the cyst with a forceps, and extract it. When the tumor sends prolongations between important organs, which may be endangered by extirpation, a mixed method will sometimes be found useful.

First, The cyst may be exposed completely; and, as near its base as possible, it should be opened: a ligature should be placed as deep as practicable, and all comprised in the ligature should be excised. *Second*, Cut away as much of the cyst as can be removed without danger, and endeavour to destroy what remains by means of cauterization. *Third*, Open the cyst, fill it with lint, and remove it by supuration. *Fourth*, When the base of the tumor cannot be attacked without danger, isolate the cyst, draw it outwards, and carry a ligature around it by means of convenient instruments. These mixed operations are especially required when such tumors are developed in the cervical region.

When encysted tumors are the result of the obstruction of sebaceous follicles, they may, on their first appearance, be cured by the introduction of a small stilet into the obliterated opening, and evacuating the sebaceous matter by means of pressure. If, to empty the tumor, much pressure be required, an incision should be made over it. But my experience does not favour the belief that repeated pressure prevents reproduction. When they are situated on the head, they are not extirpated without a little risk from erysipelas. It is not necessary to completely isolate the cyst: a longitudinal line must be made over it; it must be emptied; it must be seized at its centre with forceps, and drawn out; and it will frequently peel off with great ease.

HYDATID TUMORS.

In the infancy of art, the term was only applied to particular tumors of the supe-

rior eye lid; but, afterwards, it was extended to all serous sacs with transparent parietes: we apply it to sacs containing within them small vesicular bodies termed hydatids. Wherever cellular tissue can be developed, vesicles, variable in number, form, and colour, may be met with. These vesicles are described as (*hydatids, acephalocysts, tania hydatigena*) living beings, because of the property of nourishing themselves, moving, and reproducing. Wherever developed, the acephalocysts are contained in a cyst. This cyst, more or less dense, firm, and resistant, is sometimes fibro-cartilaginous, and may even have osseous plates developed in it. The internal surface is sometimes smooth and polished, sometimes rugous, secretes a fluid which is sometimes limpid, sometimes turbid, in which the acephalocysts float. Sometimes this cyst contains only one—it may contain seven or eight hundred of these vesicular beings. The symptoms by which the existence of hydatids is revealed are far from decisive; we can never have any certainty about it. There is one variety which is almost always developed at the wrist, under the annular ligament of the carpus, occasionally under that of the tarsus, about the olecranon, or the acromion, the tuberosity of the ischium, the great trochanter, but always around the synovial apparatus of tendons. In the wrist it is not rare to see this affection supervene in persons who, by their occupation, have the palm of the hand exposed to pressure or friction. The cyst is almost divided into two portions, the one above the other below the annular ligament; it contains a fluid in which hydatiform corpuscles float. If we press upon one or the other half of the cyst, a crepitation is felt. In the interior of these cysts small lenticular, cartilaginous-like bodies are found, the largest not exceeding the pip of an apple, the smallest not larger than a millet seed. These cysts are usually not painful; the skin over them does not change colour, unless they are accidentally inflamed.

External means, such as douches, baths, frictions, blisters, and other similar means, have no effect on them. Extirpation is impossible, from their situation. Opening the cyst, and exciting supuration, is the only efficacious means; but it is not without danger, for intense inflammation is sometimes developed around the part. A puncture has been made, a sound or director introduced and passed into the other moiety, where a counter-opening has been made; but, as a seton has been found useless, and even dangerous, I should be indisposed to advise the employment of this method. In fact, all operations in this case are of such doubtful good, that when we consider how little pain they usually

occasion, I should not advise the disease to be meddled with, unless the tumor is so large as to prove a serious inconvenience.

SARCOMATOUS TUMORS.

Sarcoma, *tumor sarcomatosus*, consists in an indolent tumor, with a regular surface, slightly hard, offering at its interior a fleshy homogeneous substance, and susceptible of being developed at any part of the body. In form they are variable; sometimes they are pediculated, ordinarily developed rapidly, and capable of acquiring considerable bulk. They possess a feeble degree of sensibility, and support considerable pressure without pain. So long as the tumor is small the skin which covers it is natural; when it becomes very large, the superficial veins enlarge, the skin is tense, red, and may ulcerate. These ulcerations may partially or totally destroy the tumor. As these structures increase, they may undergo organic changes. We believe these tumors to be caused by inflammation, or at least an irritation which is often manifested under the influence of some external cause.

At its commencement we may sometimes arrest the progress of the tumor, or even cause it to retrograde, by diminishing vascular action at the part. Leeches frequently applied, cold, counter-irritation, compression, may sometimes bring about that result: but, when the tumor is large, extirpation, the ligature of the vessels by which it is supplied, or a seton, may diminish it. The seton brings about resolution by an obliteration of the nutrient vessels, or by the inflammation which it excites, or the suppuration which it sets up.

FIBRO-NERVOUS TUMORS.

Encysted "scirrroid," or fibrous tumors, are frequently developed in the subcutaneous cellular tissue. These tumors were formerly very generally believed to be affections of the nervous cords, and had been more or less completely described by several authors; M. A. Petit, in his discourse on pain, Cheselden, Camper, Chaussier, and Descot, have since described them.

They are most commonly found in the subcutaneous and subaponeurotic cellular tissue. They may be of the size of a grain of wheat, of coffee, or a horse-bean; they are smooth, opaque, and hard; their tissue is homogeneous, and of a dull white colour, without vestige of cavity or septum, of a fibrous, fibro-cartilaginous, or cartilaginous consistency. These tumors are never the seat of any inflammation, or even of redness; the cellular tissue which surrounds them is healthy. We do not find either at their surface or in their substance a filament of a nerve,

The following case, mentioned by Dupuytren, is strongly confirmatory of this:—A woman, for many years, experienced very distressing pain in the cheek. By some persons it was supposed to be rheumatism, by others neuralgic; leeches, blisters, opium, and general bleeding, afforded very little relief. One of her medical attendants, convinced that the pain was dependent upon some affection of the sub-orbital nerve, made a section of that nerve directly after it merged from its foramen. The pain, instead of diminishing, increased, becoming almost insupportable. The patient saw Dupuytren. Passing his fingers over the seat of pain, he felt a small hard tumor, moveable under the skin, which preserved its natural colour. Pressure at that point occasioned intense pain. The small body was extirpated, and the same moment the patient was completely relieved. If this little tumor had been formed at the expense of a nervous cord, the section of that cord would probably have produced a cessation of pain. A year ago I removed such a tumor, but much larger, from the bend of the arm: the slightest pressure upon it caused intense pain, radiating in all directions; but, although I examined it with great care, I could not trace a single nervous filament communicating with it.

Dupuytren states, that although very chronic at a certain period of their existence, they tend to soften, and that then they are apt to implicate the neighbouring glands, and to be reproduced after extirpation. Women are much more subject than men to this affection. They are developed most frequently in the limbs, and especially the legs. The patient commonly experiences pain at the part long before any tumor can be felt. As they increase in size the pain becomes greater, and the slightest friction, even that of the clothes at the part, will occasion very distressing suffering. They can then be easily felt, and may indeed very slightly project. Most frequently the pain occurs in paroxysms lancinating as in cancer; if pressed upon, the pain is like an electric shock. Very often the pain occasioned by these tumors has been mistaken for neuralgia, and patients have been tortured with leeches, blisters, and still more energetic means.

Treatment.—Extirpation is the only effectual means of relieving the patient. A longitudinal incision over the tumor is all that will be necessary; the tumor is seized with a hook, drawn forward, and, with a single stroke of the bistoury, separated from the subjacent parts; the lips of the incision are brought together, and maintained by strapping. Descot recommended the application of narcotics, where the patient would not submit to the use of a cutting

instrument. He mentioned the case of a woman of sixty, who had one of these tumors on the inside of the knee. She would not consent to operation. Narcotics were applied for many months, and ultimately quieted the pains, which did not return.

DISEASES AND INJURIES OF ARTERIES.

Before we treat of the diseases and injuries, it is proper to make a few observations upon the structure of arteries. The tissue of arteries is of a yellowish or greyish colour, becoming redder as they become smaller. The consistency of this tissue varies in different arteries. The larger arteries have the thicker coats; but, relatively to their diameter, the parietes increase in thickness in proportion as they are farther removed from the heart. The parietes are stronger in the inferior than the superior extremities, and, generally speaking, the more depending the part the stronger the parietes. Three tunics compose the walls of an artery; an *external*, fibro-cellular, insensibly merging in the adjoining cellular tissue—some persons do not hold this to be a proper tissue; an *internal*, which is continuous with the lining membrane of the heart; and a *middle* one of a peculiar character.

The external tunic, the *cellulosa propria* of Haller, should be distinguished from the surrounding cellular tissue with which Monro, Mascagni, Walther, and others, have confounded it. It is moderately thick; it presents two layers, the one purely cellular, the other yellowish and coriaceous. Its fibres are oblique and interlaced, which gives them considerable power of resistance, and upon it the *vasa vasorum* ramify. This tunic is allied to the fibrous and cellular system; its internal layer gradually merges in that of the middle tunic, and its external in the surrounding cellular tissue. The *middle tunic*—regarded by some as muscular, by others as ligamentous or aponeurotic, which was constituted by Bichat as a tissue apart from all others—appears to be similar to that of other fibrous elastic organs of the economy. It is formed of transverse whitish or yellowish fibres, which represent circles solidly united together, (Beclard). Others maintain, that there are also longitudinal and oblique fibres. Hunter and Mascagni thought the fibres were not exactly transverse; Manec conceived that they were dove-tailed. In the large arteries they may be separated into many layers; they are very apparent in middle sized arteries; in the small arteries they become of a fine reddish grey, like those of the intestines and bladder. All the arteries possess these fibres: it is an error to deny their existence in the brain. This tunic is adherent externally with the fibro-cellular

coat; internally, with the inner tunic. The *internal tunic* is thin, semi-transparent, slightly whitish, dense, homogeneous, without pores or sensible intervals. It may be artificially divided into two layers, especially in large arteries. Haller and Mascagni regarded these two layers as two distinct membranes, and have termed the external *membrana nervosa*. On the internal surface of this tunic longitudinal folds may be observed; and at the level of joints transverse plicæ, which are effaced when the limb is extended. The internal surface is smooth, lubricated by a serous fluid in small quantity. The adhesion of this tunic to the middle one is very intimate.

So constituted, arteries enjoy elasticity in great perfection, which is confounded occasionally with extensibility and retractility. Their resistance is considerable, and as much greater relatively to their calibre as they are smaller. Besides these properties, they possess a vital power of contraction. This is shown by the following experiment:—If, in the living body, we comprise between two ligatures a portion of artery, and puncture it, the blood contained in that part will be forcibly expelled; in a short time after death, this does not take place. Secondly, when death happens from hæmorrhage, the arteries emptied and contracted in virtue of this vital power, resume their ordinary dimensions when life has ceased. This contraction is much more marked in small than in large arteries. The three tunics which compose the arterial tissue have different properties. Elasticity especially resides in the middle tunic, whose longitudinal is greater than its transverse resistance; this tunic is also less elastic in small than in large arteries. Contractility seems also to be seated in this tunic. The external is the most extensible; it frequently remains intact when the other membranes are ruptured, as we see in the application of the ligature. The internal tunic is little resistant, and seems to have no other obvious use than to facilitate, by the polish of its surface, the passage of the blood. If great traction be made upon an artery, the internal tunic gives way first, then the middle; the external resisting long before it is ruptured.

In their course, the situation of the arteries is such that the trunks occupy the most protected parts, and in the sense of flexion at joints, where they are much protected from external injury. They are usually tolerably direct, and are flexuous only at points where the bulk is liable to variation, or where the mobility is very great—the stomach, the uterus, the neighbourhood of joints, the iris.

WOUNDS OF THE ARTERIES.

By *wounds of arteries*, we mean not only the solutions of continuity produced by cutting instruments, but all the injuries of their parietes by any external cause. Thus we include contusions, incomplete section by ligature, or other causes. A wound may be *penetrating* or *non-penetrating*. If it destroy the external tunic only, the injury is repaired, and often without obliteration of the canal. This injury does not, as was supposed by Calisen, end in the formation of an aneurismal tumor. If, however, the external and middle tunics be destroyed, Haller believes that a dilatation of the internal tunic, so as to constitute an aneurism, is the result. He states that he had witnessed such a result in the mesenteric artery of a frog. Lancisi believes that certain aneurisms of the bend of the arm, succeeding to bleeding, were thus produced. The experiments of Hunter are decidedly opposed to this view of the subject; there may be rupture of the internal tunic, but not dilatation. Upon this point there is a singular circumstance mentioned by Guthrie, in a case of hæmorrhage proceeding from the internal jugular; the two lips of the wound were seized by a tenaculum; a ligature was placed so as not to interrupt the continuity of the vessel. The carotid was seen; its external and middle tunic were destroyed; the internal was intact: it was not tied. On the eighth day it opened, and a mortal hæmorrhage resulted. The wound of the jugular was cured, and its canal was unaffected.

If the wound be *penetrating*, it may vary—it may be a puncture, it may be an incision; in which case it may be transverse, oblique, or longitudinal—it may affect a fourth, a half, or three-fourths of the circumference of the vessel; and of course the dangers vary with the direction and extent of the wound. When a vessel is completely divided *transversely*, the blood flows rapidly. If the artery be large, the external wound extensive, and not soon united, the flow of blood usually continues until the animal dies. If the wound be immediately brought together, death follows less rapidly, or syncope may happen, and the hæmorrhage be completely suspended, or it may reappear at intervals, until the animal dies or until he recovers. If the artery be of a middle size, the chances of death are less urgent.

Difference of opinion exists as to the mode in which the suspension of hæmorrhage occurs in such cases. In 1733, Petit maintained that it was caused by the formation of a clot, of which one portion surrounded the end of the vessel whilst the other formed a central plug, which was inserted a certain distance into the canal:

thus, by its coagulation, the blood seemed to constitute an obstacle. He went a step further: he distinguished in the clot a white part, which adhered strongly to the lips of the wound in the vessel; and added, that this white substance was formed of that substance which is effused between the lips of a wound, and by which those lips are united. He attached great importance to the clot, and little to the changes which occurred in the parietes of the vessel; and until the time when Morand's opinion was expressed, in 1736, this opinion prevailed. He maintained that there was a circular contraction or puckering of the extremity of the artery; that the longitudinal fibres also contracted, and that the diameter of the canal was thus materially lessened; these two causes concurring with the clot to suspend the hæmorrhage. With the exception of so much of his explanation as attached to the longitudinal fibres, the views of Morand were sound. These views were reproduced by Sharp, in 1739. In 1760, Pouteau, and before him, Gooch, rejected this doctrine. He said that the clot could not be the principal obstacle, because it was so small; it was not the retraction of the arteries, for that was not constant. The true cause, he thought, was in the tumefaction and induration of parts around the artery, which, by compression, effaced the cavity of the vessel. This doctrine was opposed by Gooch, White, Bell; but their principal attack was directed against Petit. Kirkland and White believed that the clot had nothing to do with the suppression; that it was an obstacle to the cure. The former amputated the thigh of a horse; the hæmorrhage was commanded by circular pressure. The horse was killed, and no clots were found in the vessels, but they were contracted. White mentions a similar fact. Indeed both of these men held, that so far from being beneficial, the clot is prejudicial; for, not adhering to the vessel, it may be expelled at any moment, and hæmorrhage may follow. Jones, by his numerous and conclusive experiments, reconciled the difficulties: he shewed that the several theories to which I have alluded failed, because they were too exclusive. His experiments were repeated, and the accuracy of his results was confirmed by Beclard. He proved that the blood, the parietes, the sheath, the surrounding cellular tissue, the retarded circulation, and the secretion of organizable matter, all concurred to arrest the hæmorrhage. He proved that certain obstacles were temporary, provisional; whilst others were permanent, definitive.

Those experiments shew, that when a large artery is cut across, the blood escapes by a full jet. Immediately after

its section, the artery tends to retract within the sheath; but this tendency is at first counterbalanced by the strong impulsion of the blood. Soon, however, the energy of the circulation diminishes, and the artery is withdrawn within the sheath. The portion of the sheath then projecting beyond the vessel, does not constitute a canal with smooth walls; the blood coagulates upon the connecting fibrillæ, and the external clot is thus formed. While the external clot is forming, another thin conical clot is also formed in the cavity of the vessel; its summit directed towards the heart, its base towards the opening. If a collateral vessel be given off near this clot, it is short; if not, it is longer. Beclard compared the arrangement to that of a bottle corked and waxed. At first the contraction extends to only a very short distance from the divided point, and, according to Guthrie, if with a fine seissars this contracted portion be cut off, it bleeds anew, but gradually the contraction extends to the next collateral. Jones believed that the internal clot contributed little to arrest the hæmorrhage—sometimes even it is absolutely wanting. The external clot is of more importance; but my opinion (and it is also that of Guthrie) is, that the contraction of the artery is the agent by means of which the hæmorrhage is suspended. Still so much is certain with respect to the inner clot, that often, if it be withdrawn, hæmorrhage recurs.

Soon the definitive process commences, inflammation sets in at the divided point, lymph is poured out, and the whole is consolidated into an apparently homogeneous mass. At a later period, both clots are absorbed, and the artery begins to contract, and becomes, in process of time, converted into a ligamentous mass. At a still later period, though this is not always the case, the vessel itself becomes absorbed or converted into cellular tissue.

Such are the circumstances which are observed in the portion nearest to the heart; in the other portion, when the anastomoses are considerable, the blood escapes freely, but this depends upon the completeness of the anastomoses; they may be so deficient that the blood escaping shall appear to be venous. This was observed by Hunter and Guthrie.

Jones's observations shewed that the most distant portion was the most contracted, and the external clot the smaller. This is opposed to the opinion of Guthrie. Are there any other causes of suspension of hæmorrhage after a transverse section? Some physicians maintain that the blood itself has the faculty of transporting itself where it is required, and of avoiding passing into an open artery. Koch says the blood will choose for itself the channel

through which it ought to pass; there is, then, nothing astonishing in its being able to avoid passing by the open orifice of a vessel. The elder Koch had not tied any vessel after amputation, for twenty years. He states, that, tied or not, arteries remain completely permeable, dilated, and generally empty, up to the place of section.

It is difficult to conciliate these and other facts (for facts they are) with our ideas of the circulation. How far the absence of capillary attraction may explain it, is not easy to say. It would seem, however, that it is in cases of amputation that arterial hæmorrhage is arrested with the greatest facility. There are certain curious experiments which appear to prove that when the blood arrives at the bifurcation of an artery, it enters the branch which is intact, and does not pass along the wounded branch (Kaltenbrunner). The experiments which I have made on this subject, do not confirm that idea. In the *Journal Hebdomadaire* is a paper, by Velpeau, containing fifty-six cases of wounds of arteries, where hæmorrhage has either not occurred or has been rapidly suppressed. Some, it is true, were cases of laceration, some were gun-shot wounds, some amputations performed in cases of sphacelus; but a considerable number were cases of complete section by cutting instruments.

The puncture of an artery may occasion, at first, a considerable hæmorrhage, but it is usually soon moderated; blood escapes into the sheath, parallelism is destroyed, a coagulum is formed, the opening is blocked up, and the artery remains permeable: occasionally, however, the hæmorrhage is very obstinate, and it was in consequence of this circumstance that the ancients recommended and we employ complete section. Simple punctures have occasionally given rise to secondary hæmorrhage; Guthrie relates two cases.

ST. BARTHOLOMEW'S HOSPITAL.

*From the Report of the Commissioners
concerning Charities.*

JOINT REPORT OF MR. WROTTESELEY AND
MR. SMITH, DATED JUNE 1837.

THE origin of this establishment is referred, by Stow and other historians, to Rahere, the minstrel of King Henry I., who, having founded the priory of St. Bartholomew's upon a vacant space in Smithfield, granted to him by the king, annexed to it, about the year 1122, an hospital. Here he provided for the relief of poor and sick persons and of pregnant women; and in case of the death of the

latter, for the children who should be born there, until they attained the age of seven years. No record of this grant is preserved; but a charter of Henry I., bearing date 1133, is extant, by which certain privileges were granted to the church, to Raherus the prior, the canons, and the poor of the hospital. The tomb of Rahere still remains in the church of St. Bartholomew the Great, in Smithfield.

Alfune, a man distinguished, among other charitable works, for building the church of St. Giles Without Cripplegate, the first "hospitaller or proctor for tending the poor," used daily to beg for their relief at the adjoining market and shambles of Smithfield. The annexation of the hospital to the priory was confirmed by a charter of King John; and various grants of property, including 37 acres of ground, situate in St. Giles and St. Botolph's Without, Aldgate, in the eighteenth year of Edward II. are also recorded. In the 11th of Henry VI. an arrangement between the prior and convent of St. Bartholomew and the master and brothers of the hospital, was sanctioned by parliament, by which the execution of the repairs of the "aqueduct in Iseldon, called Cannonsbury, the water whereof was conveyed by pipes underground," was committed to the master and brothers, to be done at their cost; one moiety of the water to be conveyed to the hospital by pipes, and a rent of 6s. 8d. per ann. to be paid to the prior and convent. In 1423 the buildings of the hospital were repaired, at the charge of the executors of the celebrated Whittington.

The Valor Ecclesiasticus gives the following statement of the real property of this hospital at about the year 1530:—Rents in and near London, 229*l.* 4*s.* 6*d.*; in Middlesex, 30*l.* 11*s.*; in Essex, 38*l.* 6*s.* 8*d.*; in Berks, 12*d.*; in Northampton, 6*l.* 6*s.* 8*d.*; in Somerset, 3*l.* 6*s.* 8*d.*; in St. Alban's, 6*s.* 8*d.* Total, 371*l.* 3*s.* 2*d.*, subject to payments of 66*l.* 6*s.* 9*d.*; leaving a net income of 304*l.* 16*s.* 5*d.* per annum.

Soon after this period the monasteries were suppressed, and the property of St. Bartholomew's Spytell, as well as of St. Mary's Spytell and St. Thomas's Spytell, was for a time possessed by the crown. In 1544, after an unsuccessful petition from the corporation of the city, that the king would grant them the disposal of the funds for the relief of the sick and poor, Henry VIII. issued letters patent, by which (after stating that the hospital was then vacant, and that its property had fallen into his hands) he declared, "that there should be comfort to the prisoners, shelter to the poor, visitation to the sick, food to the hungry, drink to the thirsty, clothes to the naked, and sepulture to the

dead administered there;" erected and founded an hospital, to consist of one master and priest, and four chaplains priests; to whom he granted the site, ambit, and precincts of the hospital and church, with the goods and chattels thereof, to hold the same in pure and perpetual alms. The government of the hospital was lodged in the body thus constituted, but the possessions were not regranted to them, and it does not appear that the new constitution ever came into active operation. But in 1546, a charter was granted, after repeated solicitations, to the corporation of the city, by which the hospital was to be refounded for the reception of one hundred poor and sick persons, and was endowed with 500 marks per annum from its former possessions, on condition that the citizens should be bound yearly for ever to give other 500 marks for the same use and intent. This agreement was executed on the 13th of April, 1546.

The charter was granted January 13, 1547. By it the king gave to the corporation numerous detached pieces of property, including the hospital with its church and land, the church, lands, and precincts late of the Friars Minors, commonly called the Gray Friars—which, with houses in the adjacent parishes of St. Nicholas and St. Ewine, and of St. Sepulchre's Within Newgate, were erected into the parish of Christ Church Within, Newgate—various messuages, chiefly situate in the streets adjacent to the hospital, some yearly rents from tenements in the same neighbourhood, and lands in different counties, which had formerly been part of the property of the old hospital and convent. The hospital was to be called "The House of the Poor, in West Smithfield, near London, of the foundation of King Henry VIII."

In return, the corporation agreed to grant a residence and an income of 26*l.* 13*s.* 4*d.* to the vicar of Christ Church; a residence and an annuity of 13*l.* 6*s.* 8*d.* to the vicar of St. Bartholomew's-the-Less, and other proportionably smaller incomes to the visitor and five other priests, who were to officiate in the hospital, visit the prisoners in Newgate, &c. They also agreed to find lodging, food, and "all other things meet, convenient, and necessary," for one hundred poor folks; to maintain a matron and twelve women attendants under her; to give appropriate salaries to a visiting priest, "the hospitaller," a parish-clerk and a sexton, a steward and collector, a porter, butler, and cook. (The salaries of the five last officers were to be 5*l.* 13*s.* 4*d.* to the two first, 5*l.* to the porter and cook, and 4*l.* to the butler.) They further covenanted to find eight persons to be beadles, "to bring thither such

poor, sick, aged, and impotent people, as should be found going abroad in the city of London and the suburbs thereof, and to expulse and avoid such valiant and sturdy beggars as they should find." Lastly, they agreed that they would find perpetually one person sufficiently learned in the science of physic, and one other person having sufficient knowledge of surgery, to be continually attendant on the sick and sore people, to minister to them from time to time such things as should be needful for their sickness and diseases; that they should give and pay to the physician 20*l.* per annum, and to the surgeon the same; and that they should buy and provide all manner of apothecary's ware, and other things necessary and convenient for the making of salves, and all other things touching physic or surgery, for the help and healing of the said sick poor and impotent people.

Such was the charter for the renovation of St. Bartholomew's. Stow says that the houses which formed the bulk of the property thus granted, were for the most part decayed or leased out at inadequate rents, and that the citizens were at great expense to obtain from them the full income of 500 marks. The temporary deficiency, however, was supplied by liberal contributions, which were chiefly made at the instigation of Sir R. Dobbes, the mayor, and the same property now forms the main bulk of the resources of the hospital.

In 1548, the management of the hospital was intrusted to four aldermen and eight commoners, who were to remain in office two years; one half going out each year. Of these, one was president, four surveyors, four almoners, one treasurer, and two scrutineers. At this time, also, there were three surgeons, with salaries of 18*l.* each. In 1552, the annual expenditure, including the salaries of the clergy and the diet of the poor, at 2*d.* per diem each, was about 856*l.* per annum.

The hospital continued under the same management till 1557, when, having been previously dissociated from them, it was connected with the other royal hospitals (Christ's, Bridewell, and St. Thomas's), and placed under the same government with them, according to articles entitled "The Order of the Hospitals of King Henry VIII. and King Edward VI." In this order, a comptroller-general and a surveyor-general, both of whom were aldermen, were appointed over all the hospitals, and, for the government of each, three aldermen, a treasurer, and eight other citizens.

From this period to 1782, the corporation appear gradually to have allowed their privileges of government and control over all the hospitals to decline, or to have

made only ineffectual attempts to exert them, as the number of governors unconnected with the corporation, but whose accession to the hospitals was highly beneficial by their donations and support, increased, and assumed so much of the power of management, as left to the corporation only a formal right of confirmation of the lists of governors presented to them each year. The disputes which ultimately arose on the respective rights and powers of the corporation, and of the elected and acting governors, had principally relation to the management of Christ's Hospital, but were settled for the government of all the royal hospitals by an act of parliament, passed in 1752, entitled, "An act to render valid and effectual certain articles of agreement between the Mayor and Commonalty and Citizens of the City of London, Governors of the Possessions, &c. of the Hospitals, &c., and the Presidents, Treasurers, and acting Governors of the said Hospitals.

By this agreement between the corporation and the elected governors, confirmed by the act, all the then governors of the several hospitals were first established in the rights and privileges which they had lately enjoyed; and it was agreed that the governing body should thenceforward be composed of the elected governors, with the lord mayor, the aldermen, and to each hospital twelve of the common council, elected at one of their courts.

From the passing of this Act the entire government of St. Bartholomew's has rested with the general body of the governors, who are distinguished into chartered or corporation governors, and donation governors. The former comprise the whole court of aldermen, and twelve common council-men. The number of the latter is unlimited: they are elected from persons who have subscribed 100*l.*, or who, if proposed or nominated by a governor who has served the office of steward, have subscribed 50*l.*; in either case the nomination has to be approved at a meeting of the house-committee, and at a general court. The present list of governors contains 281 names; and the president, the treasurer, the almoners, and the different committees of management, are selected by the general court from the whole body.

Four general courts are held annually on the 4th Wednesday in January, April, June, and November; and at these are elected the president, treasurer, almoners, and three committees. Here also vacancies are filled up in any of the more important offices in the establishment.

The almoners are four in number, and each serves four years, one being elected, at each July court, from the governors who

have been or are on the house-committee. The house-committee is, in effect, the governing body of the establishment. It consists of the president, treasurer, almoners, past-almoners, and twenty-one governors, who serve two years, and of whom ten or eleven go off annually. This committee usually meets once in every month, and as much more frequently as may be necessary; they regulate generally the affairs of the hospital, subject to the approbation of the general court; they also have to approve of governors before being submitted to the same court, and to appoint such officers and servants as are not appointed at it.

There is also a committee of auditors, who meet quarterly, and an apothecaries' committee, consisting of the president, treasurer, almoners, past-almoners, and all such governors, in any way connected with the medical profession, as have been stewards at an anniversary dinner: they are summoned quarterly to direct the purchase of drugs for the use of the Hospital.

The officers of this Hospital are as follows:—

A President, whose office is for life, and merely honorary. He is usually selected from the aldermen; and the office is frequently conferred on the Lord Mayor at the time of the vacancy occurring. It is at present held by Alderman Lucas.

A Treasurer, who is annually re-elected at the July court. He has a house within the Hospital precincts, and has control over all the inferior officers and servants, with a power of suspension *ad interim* in case of misconduct. He receives and reports all moneys; and all payments above 20l. are made by him. He has to return his accounts monthly and quarterly—is a party to all investments of money, and has to survey all property previously to its being let, &c. With the exception of the unfurnished house, no remuneration is received by the treasurer; and the expenses which his office entails are greater than the advantage he receives from the balance which is allowed to remain in his hands. The office is at present held by Thomas Helps, Esq.

The almoners, whose office it is to attend every Thursday to discharge and receive in-patients, and to admit or continue out-patients: they also direct the provision of all stores, inspect and sign all bills before they are paid, audit accounts, and attend the treasurer on various hospital business. Their office is entirely gratuitous.

The Hospitaller or Chaplain, the Rev. Samuel Wix, is also vicar of St. Bartholomew's the Less, a small parish containing only twenty-eight houses, the property of the Hospital. His attendance in the Hospital consists in performing the morn-

ing and afternoon services in some of the wards on each Sunday, reading prayers daily in one ward in each wing alternately, and visiting such patients as desire his attendance at any time.

The Clerk, Mr. J. Wood, performs the various duties of secretary to the establishment. The steward, Mr. W. Wix, superintends its whole interior economy. The renter, Mr. Wilby, has the charge of collecting the yearly rents, in town and country, the tithes, and other annual payments. The surveyor or architect, Philip Hardwicke, Esq., has the general superintendence of the buildings.

The medical and surgical establishment is composed of three physicians and three assistant physicians, three surgeons and three assistant surgeons, who are appointed by the general court. There are also three resident house-surgeons, a resident apothecary, who is considered as the resident medical officer, and an assistant apothecary.

Each physician attends, at least, three days in each week; often every day, and occasionally twice in the same day. One of the physicians and one of the surgeons attend the almoners on every Thursday for the admission of in-patients. Their only emolument from the Hospital funds is a salary of 105l. each; but the pupils' fees for medical practice, and the opportunity of becoming a lecturer in the school, form a very considerable source of profit. Each physician has one, two, or three pupils as clinical clerks, who are allowed to prescribe simple remedies in his absence, and who pay no additional fee for this privilege.

The assistant physicians attend on alternate days from 11 till 2, or longer, to prescribe for the medical out-patients, and medical casualties, *i. e.*, all such as apply for medical aid without having been made either in or out-patients. Their remuneration is 100l. per annum. Each usually takes charge of the in-patients of the senior physician with whom he is particularly associated, for three or four weeks in the year.

The rules of the surgeons' attendance are the same as for the physicians; but their actual attendance is also much more frequent than is absolutely prescribed for them, a daily visit being always made by each in those weeks in which the accidents are assigned to his charge, and generally in every week more than the three visits which are required by the orders of the Court. The stipend of each surgeon is 40l. per annum; and a gratuity of 30l. is annually voted to each by the general court. A payment of 7l. 10s. is also made quarterly to one of the three for the performance of the operation of lithotomy,

and two guineas annually to each in lieu of other small privileges formerly allowed them. Each surgeon nominates six dressers and a house surgeon annually. The assistant surgeons have no duties in the Hospital, except when called upon to act as deputies for their respective principals. [Since the report was made, duties have been assigned to the assistant surgeons corresponding to those performed by the assistant physicians, and for which each of them now receives a similar salary].

The apothecary is the resident medical officer of the establishment, which he never quits without leave of the treasurer, or two almoners. He has to attend the admission of patients, both on the usual admission day and in casualties, to visit the wards morning and night, and to have the charge of the medical patients in the absence of the physician. He is also required to keep open the dispensary from 9, A.M., to 8, P.M., for the dispensing of medicines, to keep an account of the drugs consumed, &c. His salary is 400*l.* a year, and he has a house in the Hospital precincts. He is permitted to take two apprentices, but is strictly debarred from private practice.

The three house surgeons are nominated annually by the surgeons from among their dressers upon payment of a fee of fifty guineas. Their appointment is subject to the approval of the house committee and general court, which approval, however, is never withheld: they reside within the building, and are expected to be in attendance, by turns, day and night. They receive each a salary of 25*l.* per annum from the Hospital; but no allowance is made them for attendance, &c.

The dressers do not, properly speaking, form a part of the Hospital establishment, and receive no emolument from its funds. [Their duties are probably well known to most of our readers].

The sisters of the wards are twenty-nine in number, one superior attending each ward, and one attending on the casualty patients. They are to be in constant attendance on the patients, and to carry into effect the directions of the medical officers. The salaries of the majority vary from 14*s.* to 20*s.* per week; the four senior sisters receive from 22*s.* to 31*s.* 6*d.*; they have each annually a gown and a cap, and a gratuity of a guinea or a guinea and a half. A dinner is provided for them at the Hospital expense on Sundays only.

The nurses are seventy-five in number, being generally two to a single ward, and three to a double ward: they act under the sisters, and perform all the usual duties of servants. They receive 7*s.* weekly. They are allowed two gowns and

a cap each year; half a loaf and a pint of beer, and the meat from the broth daily, and a dinner on Sundays. Fifty of the number discharge, in rotation, the duty of night nurses, for which an additional 1*s.* 9*d.* per week is allowed them.

Admission of Patients.—The strict rule of the Hospital is, that patients should be received only with a petition signed by a governor, or upon a recommendation from the Lord Mayor or the presiding magistrate at the Mansion House or Guildhall, or (though this custom has now nearly lapsed) from the Board of Admiralty. The real criterion of admission may, however, be fairly stated to be the urgency of the patient's case, as not only have all cases a preference on the ordinary admission day according to the degree of their urgency, but cases of accidents are admitted at all hours without any order whatever. Foreigners are admitted on the same terms with natural-born subjects; and infants with (if necessary) their mothers to attend upon them. Thursday is the ordinary admission day. The applicants meet in the steward's office at 11, A.M., and are examined by the physician and surgeon of the week and their assistants. The most urgent cases are admitted; and those who remain after receiving as many as will fill the vacant beds in the Hospital, are, if necessary, made out-patients. Small-pox is the only disease against which the doors are absolutely closed. Fees were formerly required from each patient on admission; but, in 1821, these were abolished, and no payment whatever is now required from any patient.

The security of a householder is still nominally required, for the removal of a patient when cured, or his burial should he die in the hospital; but, in fact, not half the patients tender any security at all, and many of the householders, whose signatures are accepted, are not of such a class as to make the security available.

In the case of parish paupers, the steward applies to the parochial officers for the usual security, and for the payment of 9*d.* per day for the support of the patient; but the demand is constantly refused upon some excuse; so that for 200 or 300 patients of this class admitted yearly, the amount actually obtained for the hospital does not exceed £20 per annum.

Wards.—The hospital contains 28 wards, of which 7½ are devoted to medical and 21 surgical patients—of the latter, five are appropriated to venereal patients. The total number of beds is 533; of which 169 are for medical and 364 for surgical cases, about 60 of which, on the ground-floor, are appropriated for accidents. The patients in each department are divided equally

to each physician or surgeon, so that each of the former has always upwards of 50 patients, and each of the latter about 120. All the beds vacant in the hospital are filled up on each Thursday, with the exception of 15 or 20, which, unless in circumstances of unusual pressure, are reserved for casualties during the week. Under such circumstances, also, one, two, or three extra beds are fitted up in the several wards.

There are no wards appropriated to infectious diseases. Patients in raving delirium, or who are otherwise productive of serious annoyance to those around them, are removed to private rooms, of which there are sufficient to accommodate about four patients. Experience has shewn, that double wards (*i. e.* such as are composed of two parallel rooms opening into each other, but with only one general entrance) are managed with much greater convenience and economy than single ones.

About 130 persons, including venereal patients, apply to this hospital for admission every week; and of these the average weekly admissions, in 1836, amounted to 52 on each Thursday, and on the other days of the week to 34; making a total of about 5,500 in the year. In the same year the out-patients amounted to 8,238, and the casualties to 20,543. Each patient, on admission, is, if necessary, washed in the warm bath; his money, if, as it rarely happens, he has any, is usually taken charge of by the steward; his clothes, if very ragged or filthy, are destroyed, and new ones supplied. Directly after admission he is visited by the physician or surgeon in attendance, or, if received at times when they are not present, by the apothecary or house-surgeon, and the necessary medicines, diet, &c. are ordered.

Funds of the Hospital.—The total amount of contributions, in money, for the general purposes of the hospital, up to September, 1836, had reached upwards of £195,000, exclusive of nearly £41,000, subscribed for the special purpose of erecting the present buildings of the quadrangle of the hospital between the years 1729 and 1748. The total pecuniary contributions, therefore, have been £236,019. 7s. 6d.

The actual property of the hospital is as follows:—

The rental of the houses belonging to the hospital, in London and its immediate vicinity, comprising the earliest acquired and the larger portion of the estates, which are chiefly situated in its neighbourhood £17,011 19 1
Rental of the landed estates of the hospital, situate in different parts of the kingdom, let on farming leases, or at a rack-rent. 6,187 2 7
Quit-rents, comprised in the

charter of Henry VIII., and rent charges, with annuities and fixed payments not charged upon land	1,119	19	10
Land-tax redeemed,	635	4	4
Tithes of the parish of Christ Church, within Newgate	186	18	1
Dividends on stock	5,236	11	4
Casual and fluctuating sources of income	787	19	9
	<hr/> £31,165 15 0		

The average income of the six years, including 1830 and 1835, was upwards of £32,170, and the balance brought forward each year averaged between £6000 and £7000.

From the expenditure for the same period it may be sufficient to extract the sums appropriated to the more important purposes, among which we find—

	£	s
Charges on account of the estates (average about)	2825	0
St. Bartholomew's Church	407	11
Christ Church	106	0
Tradesmen's and workmen's bills for repairs and new buildings, furniture, stationery, oil, candles, &c. about	5600	0
Provisions, about	4700	0
Apothecary's shop	3750	0
Salaries to officers and sisters, about	4850	0
Wages to nurses, carpenter, watchmen, &c.	2600	0
Annuities, gratuities, and pensions	750	0
Coals	800	0
Hospital dinners	350	0

With other more variable or less important expenses than the above, the average outlay of the hospital in the same six successive years has amounted to upwards of 33,160l.

Of the provisions, the meat, bread, butter, beer, and milk, are supplied by contracts, which are usually entered into half-yearly, and invited by public advertisement.

The supply of articles for the apothecary's shop is managed by the apothecary's committee. It is usual to make up in the hospital all the compound substances, which are consumed in such quantities that they can be prepared in the laboratory more cheaply than they can be purchased; and a circular is usually sent to some of the chief London druggists, inviting them to send samples of the different articles required, with their prices. From these the committee, assisted by the lecturers on chemistry and materia medica, make a selection.

The only instance in which the hospital has been supplied with stores, or materials to any extent, by a governor, appears to be in the article of drugs. For the eight years preceding 1836, an average of one-fifth of the drugs were purchased of a governor; but no governor by whom a sample is sent in is ever summoned on the committee for the selection of the articles.

Medical school.—The introduction of lectures at this school is of very recent date, and but little prior to the erection of the anatomical theatre in 1822. Mr. Percival Pott about seventy years ago delivered occasional lectures; but the late John Abernethy may be called the founder of the present system, within so short a period as eighteen years from the present time (1836). In 1822, Mr. Abernethy first proposed to the governors that the collection of anatomical preparations which he had formed, and the library, which he and the other surgeons had principally contributed to accumulate, should become the property of the hospital; and that, in return, the governors should provide greater facilities for instruction to the pupils than the existing buildings afforded. Mr. Stanley became joint lecturer with Mr. Abernethy about 1824; and with this gentleman's consent the above arrangement was carried into effect in 1828, and the museum was presented to the governors. It has been since maintained and increased entirely under the eye of Mr. Stanley, and from the produce of the anatomical lectures delivered by him. It is open daily to all the pupils of the hospital and attending lectures, and (by the courtesy of the officers) to strangers.

For the buildings intended to facilitate the communication of medical knowledge, the governors have devoted a portion of their funds, not exceeding in the whole 5000*l.*; and "to us it certainly appears that the immediate benefit arising to the patients in the establishment from superior skill and science in those pupils who give subordinate assistance in the situation of dressers, and the incentive to diligence and attention afforded to the principal medical officers by the constant presence of so many keen observers as are thus brought around them, independently of the inappreciable good effected by the general diffusion of medical knowledge, fully justify the application."

On a vacancy occurring in a lectureship, the medical committee, consisting of the physicians and surgeons, with the assistants who are lecturers, meet and agree upon the party whom they shall recommend to the house committee; and if the latter approve of the nomination, it is submitted to the general court.

ON THE FREQUENCY OF THE PULSE AT DIFFERENT AGES

IN MALES AND FEMALES.

By W. AUGUSTUS GUY, M.B., Cantab.,
Professor of Forensic Medicine, King's College,
London.

THE knowledge which we possess of the frequency of the pulse at different ages is altogether unworthy of medicine, considered as a science, and unequal to its requirements as a practical art. A few careless estimates, for the most part very wide of the truth, and some calculations founded upon incorrect data, make up the sum of our information. The only parts of the subject which have been examined with any care are the pulse of the fœtus, of the child during the earliest periods of life, and of persons in advanced age; the rest is a mere blank. The works which have been written on the pulse are not only barren in general results, but they furnish very few materials which can be made available to the building up of a science. It was necessary, therefore, to have recourse to observation, and to collect a large number of facts before any progress could be made in this department of physiology. The observations which I had already collected, with a view of illustrating the effect of posture on the pulse, supplied me with a large number of such facts, and formed a strong inducement to add to them, and to make the frequency of the pulse at the several periods of life the subject of a separate essay.

The observations contained in the annexed tables have been derived from different sources. By far the greater number have been collected by myself, a few have been contributed by friends, and a still smaller number have been taken from books. Of the observations which I have myself collected, a large proportion, at all ages, have been made on my friends and acquaintances; the rest have been obtained in schools and workhouses*. The observations

* I must here acknowledge my obligations to my friend Mr. Reid, of Bloomsbury-square, for the opportunities which I have enjoyed in St. Giles's Workhouse. I have also to return my best thanks to Mr. Burgess, the apothecary of that institution, for his obliging assistance; and Mr. Hewett, the master of the Holborn Union, for the facilities which he has afforded me.

gleaned from authors, or contributed by my friends, were made under the same conditions, and with the same precautions as my own. The twenty-five observations on the pulses of children, under one week old, have been drawn chiefly from books; and the works of Floyer, Falconer, Nick, &c., have contributed some observations on persons of advanced age.

The observations were made between the hours of 11, A.M., and 2, P.M. Those collected in schools and work-houses were taken between 11 and 12; the remainder, for the most part, between 12 and 2. A few observations taken from authors were made before breakfast, fasting. All the parties examined were in the sitting posture, except the children under a week old; and some few of the old persons of both sexes, who, though in the enjoyment of good health, were bed-ridden. These were examined in the recumbent posture. In every instance the subjects of the observation were in apparent good health, in a state of rest, unexcited either by food or exercise. I was very careful to exclude all those cases in which I could detect any symptom of ill-health, or any source of excitement*; I also waited some time to allow the pulse to regain its natural frequency, when it appeared accelerated by fear or timidity.

The pulse, therefore, was taken, with the exceptions already mentioned, in the sitting posture†, in the middle of the day, and in a state of complete rest.

In the subjoined tables the several observations have been arranged in the order of their magnitude, the highest pulses being placed at the heads of the several columns. It has seemed advisable to publish all the facts, as well as the results obtained from them, that any one who is disposed to form a more extensive induction may add his own materials to mine. I am by no means inclined to regard these facts as sufficiently numerous, and I propose accordingly to add to them as opportunities offer themselves; in the meantime they will form a near approximation to the

truth, and furnish more precise information than any at present existing. That I might make the tables more complete, I have added a column containing the pulses of children less than one week old. In this column the sex is disregarded; and I have ventured to assume, for the present, that, at this early period, the influence of sex is not very considerable, an assumption which is fully justified by a comparison of the pulses of the two sexes during the first seven years of life. In the arrangement of the tables I have preferred septennial periods as corresponding with the most approved division of human life. The want of a sufficient number of observations on healthy persons, beyond 84 years of age, has prevented me from extending the tables as much as I could wish.

The following Table presents the maximum, minimum, and mean frequency of the pulse, in healthy males, at the several ages specified; as well as the range of the pulse; that is to say, the difference between the lowest and the highest number:—

Age.	Max.	Min.	Mean.	Range.
1 week	160	104	1 28	56
2 to 7 yrs.	128	72	97	56
8 - 14	108	70	84	38
15 - 21	108	60	76	48
22 - 28	100	53	73	47
29 - 35	92	56	70	36
36 - 42	90	48	68	42
43 - 49	96	50	70	46
50 - 56	92	46	67	46
57 - 63	84	56	68	28
64 - 70	96	54	70	42
71 - 77	94	54	67	40
78 - 84	97	50	71	47

There can be no doubt, that if the facts from which these numbers are obtained were more numerous, the maximum, minimum, and mean frequencies would present a more regular increase and decrease. As it is, the maximum and the mean frequencies present a progressive decrease during the first seven periods, and the minima during the first five periods. It will be seen, also, that in old age the pulse becomes more frequent, though the increase is not regular, and is shown chiefly in the maxima.

That the values obtained from the twenty-five observations recorded in the tables form close approximations to the true values, may be inferred from the

* In feeling the pulses of the poor as well as of the rich, I took care to exclude not only all those who had taken food since their breakfast, or exercise immediately before the observation, but those who had smoked tobacco, as this is among the most powerful excitants of the pulse.

† For the sake of accuracy I may state that the back was unsupported.

near accordance of the numbers with those derived from fifty observations. This will appear from the following comparison:—

No. of Observns.	Age.	Max.	Min.	Mean.	Range
25}	2 to 7	128	72	97	56
50}		128	72	97	56
25}	8 - 14	108	70	81	38
50}		108	68	85	40
25}	15 - 21	108	60	76	48
50}		108	60	78	48

The following Table shows the frequency of the female pulse at the several periods:—

Age.	Max.	Min.	Mean.	Range.
1 week	160	104	128	56
2 to 7 yrs.	128	70	98	58
8 - 14	120	70	94	50
15 - 21	124	56	82	68
22 - 28	114	54	80	60
29 - 35	94	62	78	32
36 - 42	100	56	78	44
43 - 49	106	64	77	42
50 - 56	96	64	76	32
57 - 63	108	60	77	48
64 - 70	100	52	78	48
71 - 77	104	54	81	50
78 - 84	105	64	82	41

From this Table it appears that though the variations in the maxima and minima are as great as in the case of the male pulse, the minor frequencies present a regular decrease up to 56 years, and a progressive increase from that period up to 84 years of age. That these numbers also are a near approximation to the actual frequencies of the pulse at different ages will appear, as in the case of the male pulse, from the following comparison of the results of twenty-five observations with those of a larger number:—

No. of Observns.	Age.	Max.	Min.	Mean.	Range
25}	8 to 14	120	70	94	50
50}		120	70	95	50
25}	15 - 21	124	56	82	68
45}		124	56	80	68
25}	71 - 77	104	54	81	50
45}		104	54	80	50

If we regard the occasional irregularities in the decrease or increase of the pulse at the several periods as the necessary consequence of a limited number of observations (a defect which a more extended induction will probably re-

medy), we may state the general result of the above facts in the following terms:—

The pulse falls rapidly during the first seven years of life, less rapidly from 7 to 21, and less rapidly still from 21 to 35; from 35 to 56 it remains nearly stationary, and from 56 to 84 again increases by a few beats. This statement is in strict accordance with the frequency of the female pulse at different ages, and it is probable that it will agree with the male pulse when a greater number of observations shall have effaced the irregularities at present existing. On comparing the male with the female pulse, it appears that

1. The female pulse differs little from the male pulse during the first seven years of life, but after seven years of age the mean pulse of the female exceeds that of the male by from 6 to 14 beats, the average excess being 9 beats, or about one-eighth of the mean frequency in the male.

2. The minimum frequency of the female, at more than one period of life, falls below that of the male, but its maximum frequency is, at all periods, above that of the male.

3. The range of the pulse in both sexes is considerable: in the male it extends from 28 to 56, in the female from 32 to 68 beats; and it is probable that more numerous observations will extend this range still farther. The average range in the male is 43, in the female 48. The observations contained in the tables by no means tend to increase the confidence which the medical man places in the pulse as an indication of disease; on the contrary, they confirm the opinion generally entertained of its extreme fallaciousness. It must be borne in mind, however, that there are two distinct sources of fallacy connected with the pulse; the one inherent in the subject itself, the other dependent on the imperfect manner in which it has been investigated. The former source of fallacy will be increased rather than diminished by every considerable addition made to our facts; the latter will disappear entirely when our facts become sufficiently numerous. Hitherto our knowledge of the frequency of the pulse, at different ages, has been limited to a few rude guesses at the average frequency at one or two periods of life. The maxima and minima have been entirely overlooked; and yet these alone can supply us with data which may

be implicitly relied upon in our investigation of disease. If a sufficient number of observations were collected to determine the maximum and minimum frequencies, consistent with a state of health, at the several ages, it is obvious, that wherever the pulse exceeds the one extreme, or falls short of the other, disease is present, provided that the body is in a state of complete rest. Wherever, on the contrary, the pulse is within the limits of the two extremes, its indications must be extremely fallacious, unless we are acquainted with the frequency with which the pulse beat in a state of health.

It appears from the foregoing remarks, that the present essay has done little more than confirm the prevalent belief in the fallaciousness of the pulse; but by placing some limits to its uncertainty, it has substituted a distinct and well-defined conviction for a vague and general impression; and this is perhaps the only practical improvement of which this and kindred subjects are susceptible. It is by no means improbable, however, that the uncertainty connected with this subject may be in some degree removed by very careful observations, made with a view of ascertaining the influence of temperament, stature, &c.—influences which it is no part of my present object to examine.

In making any practical application of the facts contained in the tables, allowance must be made for the effect of change of posture, if the pulse is examined in the erect or recumbent position.

[Here follow five very elaborate tables, which we regret we cannot give. Indeed, three of them (a page each) would have required to be engraved, as they could not be made up in types. We trust and believe that the author's views are rendered intelligible by what we have given.—ED. MED. GAZ.]

A SHORT ACCOUNT
OF
OPHTHALMIA;
PARTICULARLY AS IT OCCURS IN MALTA.

BY FREDERIC ROBERTS,
Assistant Surgeon, 59th regiment.

INTRODUCTORY REMARKS.—The discrepancies respecting the sources of ophthalmia in this island, have led to a brief inquiry what results numerical calcula-

tions might discover to us in illustration of the history of the disease, and how far the cause of the same may depend upon atmospheric constitution. For this purpose we have placed in juxtaposition the state of the thermometer and barometer, and shown the prevalence of certain winds, and the number of rainy days, in each month—presenting, in a tabular form, the relation the constitution of the atmosphere (thus far) stands in to the number of admissions, with this disease, into the civil and military hospitals of the island.

After shewing to what extent several physical agents may operate, and the circumstances under which they may become influential, we shall consider the nature of the propagation of the disease.

Our object in this article, then, is the application (without doubt very defective) of the statistical test in attempting to fix the cause of ophthalmia in this island, and to show what facts the superficial investigation of our subject permits, as, from the short period we have included, but an incorrect average can be formed of casualties of this sort: still we presume that comparative instruction may be received from small estimates; at the same time, however, admit some uncertainty in the character of our evidence as to the exact period of greater endemic prevalence of the disease, which we shall further notice as we proceed.

On the influence of temperature.—Heat alone has never been considered as the source of ophthalmia in any country, though, in conjunction with strong light, it has frequently been surmised to be so; for it is well known to give rise to amaurosis and nyctalopia, and to produce otherwise much impression on the eye. In looking over the register of the thermometer for each month, commencing with July, 1836, and comparing the number of admissions, we cannot draw the conclusion that they stand in the relation of cause and effect, inasmuch as the admissions during the hot months bear no proportion to those when the heat is less*. And if the primary cause depended upon excess of heat alone, we should expect to find the disease most prevalent when the heat was greatest, as in the hot months of July, August, and September, when the admissions are not always so

* See table at the end.

numerous, in proportion to the degree of heat, as later in the year. That the influence of heat, in conjunction with great glare from the barren and rocky nature of the island, may be presumed, is plausible, inasmuch as the admissions from the country of the labouring classes into the dispensary in the months of July, August, and September, are very numerous*. This supposition is further strengthened by the circumstance, according to the information afforded by the books of Civil Hospital, of the admissions from the country, where the inhabitants are more exposed to insolation, greatly exceeding those from the town, where, again, the inhabitants are much less exposed to the sun. Indeed, out of 250 children in the House of Industry, where little exposure to the sun occurs, and where segregation is established when a case happens, I am informed that there occur but very few cases of ophthalmia in the year: and out of 584 men and women in the poor-house, where the like system of segregation obtains, and where certainly the inmates are old, but six cases of acute and chronic ophthalmia occurred in three years and a half. Amongst the better classes also very few cases happen; but in the poor and military population, a great many.

The period when the influence of heat and light come mostly into operation is in the spring, when people forget that they are exposing themselves to a much greater heat and glare than usual, and to which the extreme intolerance of the same, as the season advances, only prevents them from further exposing themselves. The like again occurs in the autumn, when, with the same obstinacy and perverseness, people think the heat, from it so happening for a day now and again, is abating. This is the more probable when we consider how much the soldier (in whom it is so prevalent) is thus exposed. And again in females, in whom the following table of admissions shews the disease to be twice as prevalent as in males.

Admissions of ophthalmia cases among the civil population.

	Males.	Females.
1836	44	64
1837	58	101
1838	111	184
1839	163	300

* The place of residence of each patient is entered in the admission-book.

N.B. The admissions in 1836 are only for six months, commencing 1st July, and ending 31st December.

This disparity, we are inclined to think, occurs from females not indulging so much in the siesta or day sleep as the men. (protected from the mid-way sun and its glare in the house or shade,) and becoming the victim by domestic occupations requiring this sacrifice in a measure.

We have no numerical proof of its occurring frequently in children, by reason of the imperfection of records to this effect; but, from our own observation, and the traditionary history of the disease, and, indeed, were we acquainted with the relative ages of the population, &c., even from the present tables, we presume it would found to be in a higher ratio in children than in adults, which we should attribute, in a great measure, to insolation by running out of doors in summer, &c.

The greatest extremes in heat and cold take place in March, June, September, October, and November, amounting to a difference of 13 and 14 degrees in the month. Thus the range of the thermometer indicates but an inconsiderable transition from heat to cold, though, however, cold is occasionally very sensible to our feelings when the westerly and keen northerly winds blow in a continued stream against the surface of our bodies. But whether that condition of things termed "checked perspiration," said to be produced by a sudden transition from heat to cold, is likely to be favoured in this island, where the temperature does not dispose, by extreme changes, to any very sudden irregularity in the function of perspiration in this way, is doubtful. To suppress evaporation, or the physical process of perspiration, extreme humidity and a high external temperature are essential; and the nearest approach to this condition of atmosphere is found in the sciroc wind, which again, by virtue of this condition, increases the perspiration by transudation, which depends upon causes inherent in the living economy, but which may be modified by external agents.

The sciroc wind is often warm, moist, and occasionally but little agitated. The hygrometric state of the air at this time, however, we have no means to show. But, supposing that the relative temperatures of the air and of our bodies

were such as to prevent evaporation, there is still that state of things that may be unfavourable to the healthy condition of the body, which, according as the sweat becomes abundant, it spreads over the body, and forms an external layer, which, intercepting the contact of air with the skin, prevents evaporation from the body, and admits that only which takes place at the expense of the layer of sweat always supplied by transudation. However, we can perceive that during this wind, admitting the humidity of the air then, a sudden refrigeration may be produced when the wind rises and sun sets, or when the thermometer falls, constituting a damp cold; to the extent as to diminish the perspiration by transudation, we cannot establish*.

Seeing that we cannot satisfactorily prove any sudden derangement in the function of perspiration, by influence of the physical agents, we should rather say, therefore, that, when the circumstance is favoured, after exposure to relative cold and moisture of the night, especially during sleep, when the power of generating heat is least strong, and that, upon the re-establishment of the inactive circulation in the capillaries, the vessels of the conjunctiva may undergo some comparative increase of injection in its vessels as to amount to the proximate cause of ophthalmia; and more especially when the westerly and northerly winds prevail, which they do as well in summer as winter: it blows frequently a very strong breeze, which, coming in a continued stream, may affect the eye in nearly a similar manner; by irritating the conjunctiva, increase the circulation of, distend its vessels, and produce a catarrh thereof.

On the indications of the Barometer.

—It seems, by the tables, that more changes take place in the elasticity and excitement of the atmosphere in the winter and spring months, and that it preserves a comparative uniformity of pressure during the rest of the year. In no instance does the difference amount to one inch either in the month

or year; whereas, in England, it is two or three inches; and there a variation takes place on a slight change of weather. We can find no connexion with any change in this condition of the atmosphere, and the occurrence of ophthalmia.

On the quantity of rain.—We have no other means than the number of rainy days to ascertain the quantity of rain that falls in the year. It will be seen from the tables that, on the average of three years and a half, the greatest number of rainy days occurred in the months of January, February, March, April, October, November, and December; and the least in June, July, and August. In the two former of these last named months, as indicated by the tables, ophthalmia does not appear to have prevailed much, but in the latter it begins to show its ravages with some influence, and continues its effects with greater vehemence during the next month, September, when but little rain falls. From this state of events a new agent incidentally presents itself, viz. the minute particles of dust that are blown thickly through the air during the summer months, when, as we have before observed, the westerly and northerly winds blow occasionally with great force. From the want of rain to keep down this dust, it may be presumed that it comes into operation as a mechanical agent in producing the disease. Although the circumstances of the occurrence of ophthalmia, and the blowing about of this dust, do not always correspond, which goes only to strengthen the opinion, which we shall more particularly notice in our concluding remarks, that ophthalmia (inasmuch as we adopt this as a plausible but not exclusive cause of the same) is not propagated so much by the endemic influence which originally produces it, as it is by other means.

Night dews have been mentioned as a frequent cause of ophthalmia. As no dew is ever found on the body, by reason of its high internal temperature, it is probable that this notion has continued to be entertained by authors, as handed down to them by writers of old, who supposed dew to *fall*, and to act, which it would, if it fell, as a refrigerating agent. May not such radiation of heat take place from the surface of our bodies, and especially from those parts uncovered, such as the face, during the starry and moon-light nights, with a cloudless sky, as to produce an injurious refrigeration?

* We must explain that, although the calorific function is intimately connected with the vital process of perspiration, and that the effect of cold may be to benumb the function of regeneration of heat, it is not supposed that perspiration, taking both the physical and vital processes connectedly, suffer any obstruction; for if the one is arrested, it will be observed that there is scarcely any possible case when the other is not increased, and so a due balance preserved; and therefore ophthalmia is not likely to be the effect of obstructed perspiration.

On the influence of the sciroc wind.—The scirocco, or south-east winds, it will be seen, prevail mostly in the spring, autumn, and winter; but most constantly in the autumn, and the beginning of winter: occurring, however, more or less throughout the year. Dr. Hennen considered these winds “as one of the causes of the frequency of ophthalmia,” and “that they operated most powerfully in the production of relapses.” Besides predisposing the body to take on, in connection with and when exposed to exciting causes, this action in the eye, we have seen that an injurious refrigeration may take place when the thermometer falls, which, however, is not often the case when this wind prevails. As their prevalence does not always coincide with the presence of this evidence, or is it greatest when they prevail the most, it would thus appear to want that universal influence, and which we should expect to be exerted more generally, and affect all classes, which it does not appear to do. The wind is hot and moist, and its physical action on the surface of our bodies would probably be the same as moisture, and a high external temperature (which more generally prevails than cold when these winds blow) at all times. It has also a decidedly depressing influence, probably by the sweat, supplied so freely by transudation at this time, intercepting the contact of air with the skin, and preventing the vivifying influence of evaporation from the body; rendering it less fortified against the cause of the disease too.

Having thus shown how far these several agents may probably operate, and failed to establish any *facts* further than what is already known, and as we can trace no decided connection between any particular constitution of the atmosphere and the co-existence of ophthalmia, we must then look what other causes there may be: for example, we must observe whether there is any peculiar habit among the people, or whether they are exposed to any particular mechanical or other cause, which may originally produce the disease, but which may be propagated by another.

In the history of the disease, certain phenomena present themselves which strongly incline us to consider that it is propagated by some other cause than a *universal* endemic influence, if we may so express ourselves, which should exercise

its powers more generally; in fact, that it is propagated by contagion. In favour of this argument many facts may be adduced. In different regiments, stationed here from time to time, it was observed to become epidemic amongst the men, and to continue so for an indefinite period, without reference to the seasons, but with, it is said, some diminished vehemence of character; while no such phenomena were observed among the other regiments at the same time in the same garrison. The propagation of ophthalmia by actual contact, and by its miasma floating in the air, is peculiarly favoured in a community like a regiment, where the men are necessarily obliged to live in crowded rooms, furnished with articles fabricated from wool, and supplied at best with but confined masses of atmospheric air, both which are known to retain such poison long. Considering the long time the men are confined to their barrack-rooms, often constructed in bomb-proof buildings not permitting the advantages of ventilation, it is but a natural consequence that such a disease should spread so widely, without proper segregation and strict medical police, which alone will arrest the progress of it, when it once attacks a body of men like a regiment of soldiers.

A native practitioner, belonging to a public institution, tells me, that when ophthalmia occurs in one member of a family, it is frequently observed to extend itself to the others; in which, he supposes, it is favoured by the careless and filthy habits the native poor are prone to: and its appearance and great prevalence in children, and its limitation so much to the poor and military population, would incline to the conclusion, that it was propagated by contagion, whatever its mode of operation. The circumstance of its occurring so much in children of a very tender age, likewise leads us to doubt that night air has much to do with its production, as we should scarcely expect that they would be much, or at all, exposed in that way.

In our own corps we had, last year, the opportunity of observing, that the disease commenced among the children, extended itself to the women, then the married men, and, lastly, the single men of the regiment. In giving this course of the disease, we do not mean to assert that it preserved it so true as to be without exception to this order of succession;

but it certainly preserved this order as to be very conspicuous.

The history of the disease affords evidence likewise that the preponderance of cases were in females, and it is presumed to be so in children; which may be accounted for by its spreading by contagion by reason of the close intercourse existing between them.

The ancient custom of treading out corn with cattle, still in use in this island, and winnowing in the open air, whereby the broken husks get into the eye, have been mentioned to me as accidental mechanical causes of ophthalmia among the peasants.

These incidents may, then, throw some doubt upon what is the exact period of prevalence, depending on periodical and endemic influence, of the disease; and renders it more difficult to determine this period, and consequently the cause of the disease.

We may incidentally mention, that the character of the disease is conjunctival inflammation, with muco-purulent secretion, attended with a sensation of roughness of conjunctiva, with circum-orbital and supraorbital pains, as well as pain in the ball of the eye; becomes occasionally deeper seated, and involves the iris and scleroticæ. It is much modified at times, without any apparent reason; being much less violent one year than another, and much less prevalent also. It is remarkable, that, in the year 1837, as is shown in the table below, both the troops and natives were more exempt from it than usual. It will be recollected, that this was the year the cholera prevailed in Malta. This incident must be considered, as has been observed both by ancients and moderns, that "while the tyrant disease prevailed it usurped complete dominion, and suffered no other disease to appear of an epidemic character."

TABLE, showing the Admissions for the last Six Months in each Year among the Civil Population.

	1836.	1837.	1838.	1839.
July.....	42	8	24	30
August.....	31	20	66	64
September...	26	9	93	105
October....	30	17	76	120
November...	14	20	40	63
December ..	28	13	41	33
Total....	171	87	380	415

TABLE, showing the Admissions for the last Six Months in each Year among the Troops.

	1836.	1837.	1838.	1839.
July.....	15	1	11	9
August.....	14	1	22	11
September...	9	1	25	14
October.....	9	2	29	24
November...	5	7	16	10
December...	11	7	25	6
Total....	63	19	128	74

The cases in the tables were nearly all acute. Indeed, there are scarcely any chronic; all those that were written so in the books were copied into our tables, and mixed up with the rest. No cases of palpebral ophthalmia were entered into the tables.

We consider the tables showing the admissions among the civil population but an uncertain test of the ratio of prevalence of the disease in the population, which amounts to 30,000 in Valetta, and that of Malta, exclusive of Gozo, to 120,000; as, of course, there are many who never seek relief at all for the disease: therefore all the cases that occur do not come to the knowledge of the surgeon, much less registered in public documents. But we may fairly presume it to be so; as, according to the common course of things, the greater number would seek relief when the disease was most prevalent.

It is among the military population, which on an average amounts to 2,500 men, among whom every case that happens is registered, that we must look for a more correct standard of prevalence; which we see fairly corresponds with that, whatever its correctness, among the civil population.

The following Table gives the ratio per 1000 among the Troops:

Ratio per 1000...	1836.	1837.	1838.	1839.
	$25\frac{1}{2}$	$20\frac{2}{5}$	$68\frac{1}{2}$	$68\frac{2}{5}$

The admissions in 1836 are only for six months.

ON THE PROOFS

OF THE

PRESENCE OF FREE MURIATIC ACID IN THE STOMACH,

During Digestion.

By ROBERT DUNDAS THOMSON, M.D.
Physician to the Blenheim-Street Free Dispensary and Infirmary.

This constituted the substance of a communication made by the author to

the chemical section of the British Association for the Advancement of Science, at Birmingham, in August last. The object which the author had in view in this paper, was to shew that the modes hitherto adopted of determining the quantity of free acid were liable to objection, from the circumstance that a material action in the process adopted takes place, of which he has been the first to point out the source. It is possible even that the facts he has ascertained may invalidate altogether the experiments from which the inference has been drawn, that free muriatic acid exists in the stomach. The method which Dr. Prout, and Tiedemann and Gmelin adopted, for ascertaining the quantity of free acid, was to filter the contents of that viscus—to precipitate a portion of the fluid which passed through the filter, by means of nitrate of silver. This afforded an index of the total quantity of chlorine, both free and united. A second portion of fluid was then taken, and heated to redness. The residue was dissolved in distilled water, and precipitated also with nitrate of silver. The difference between the quantities of chlorine contained in these two precipitates of the silver salt was taken as indicating the amount of free acid existing in the fluid contents. Now this mode of determining the question in view appears to be correct, if it were not liable to one objection—viz. may not the loss be occasioned by the decomposition of the common salt during the process of ignition? It is well known that common salt, when exposed to a strong heat, sublimes. It is also known that when steam is passed slowly over common salt in a state of ignition, muriatic acid fumes are disengaged. Further, it has been ascertained, that if anhydrous sulphuric acid be heated in contact with common salt, a portion of the sulphuric acid is deoxygenized, and gives origin to sulphurous acid; the free oxygen passes to the sodium, and forms soda, while the chlorine and sulphurous acid are disengaged; the remaining sulphuric acid, combining with the soda, gives origin to Glauber salt.

Dr. Thomson has pursued the investigation of these decompositions, and has ascertained, that when oxalic acid is heated in contact with common salt, even at a temperature much below ignition, a very considerable decomposition is the consequence; copious fumes of

muriatic acid are disengaged, and carbonate of soda, in a proportion relative to the quantity of muriatic acid evolved, remains behind. Tartaric acid also gives origin to a similar decomposition: with citric acid, copious fumes are disengaged, possessing all the characters of muriatic acid gas, and leaving a residuum of a black colour, which effervesces strongly with dilute acids.

Many other substances exhibited similar phenomena when exposed to the same action in contact with common salt. Saliva appeared to produce some evolution. But with animal substances, the fumes of decomposed matter are so dense and carbonaceous, that the determination of the point is involved in much difficulty. It is quite obvious, however, that the presence of vegetable matter in the stomach cannot fail to interfere with the determination of the amount of free acid in the stomach, according to the process hitherto adopted, if it does not prove altogether erroneous.

There is still another objection to the experiments of Prout—viz. that nitrate of silver will throw down some animal matter from the filtered contents of the stomach, which will certainly interfere with the true weight of the chlorine deduced from the precipitation of the silver salt.

The probable deduction from these experiments would appear to agree with the results of the researches of Schultz, who asserts that there is no other acid in the stomach, existing in a free state, except lactic acid. For the presence of this acid, the recent experiments of Fremy seem to afford an explanation. He has found that the internal membrane of the stomach of the calf is capable of transforming any aqueous solution of sugar into lactic acid. Gay Lussac, however, is not of opinion that this change is an organic one, since it is possible that the transformation may be due to an action purely chemical between the saccharine and organic matter. Indeed we know several instances in which lactic acid is produced by the contact of animal with vegetable substances. It is not so easy to account for the production of free muriatic acid in the healthy state, although there is strong evidence of its being secreted on mucous membranes in the inflammatory state of these textures, as has been shewn by the author. The investigation of this subject is pregnant with the

highest interest to science, since it must be obvious to the most superficial observer, that the solution of the grand question of the nature of the process of digestion can alone afford the key to the nature of most of the diseases to which the human body is subject.

OBSERVATIONS

ON SOME OF THE

CHANGES WHICH ARE PRODUCED IN
THE FORM AND STRUCTURE

OF THE

INFERIOR PART OF THE ABDOMINAL
PARIETES,*By Inguinal and Femoral Herniæ &c.*

BY THOMAS MORTON, ESQ.

Formerly one of the House Surgeons of University College.

THAT an accurate and minute acquaintance with the anatomy of the numerous and varied structures which compose the human body, in their normal and healthy condition, is essentially requisite to the perfect education of every member of the medical profession—no matter what particular department of the science he may afterwards select as the principal object towards which he shall turn his attention, or to the practice of which he may propose to confine himself—I believe no one will be inclined to deny, since we have the authority of the most eminent and distinguished professors of the art, in every age and country, united upon this question, and all bearing their strongest and most unreserved testimony to the truth and correctness of this opinion. Many, indeed, go still farther, and endeavour to show, and not without strong reason too, that the greater number of the most striking and valuable improvements which, in modern times, have been introduced into the practice of our art, have followed, as the certain result, a more careful and correct inquiry into the anatomy of the human frame than had been previously insisted upon; and that it is by establishing strict comparisons between the healthy condition of the various parts of the body and the changes of form and structure which have been induced in them by disease, that we have been enabled to trace back the successive steps of the morbid alterations

to the original point of their departure, and thus to bring, as it were, the whole power of our therapeutical means to bear upon the primitive source of the disorder, to effect the cure of which constitutes the principal aim of our labours.

When we consider, indeed, even though it be for a single moment, how difficult it frequently proves to be for the best educated and most experienced of the members of our profession to recognise, with certainty and exactness, structural disorder while it is as yet in its commencement, and when the distinctive characteristics of the disease are but faintly expressed, on account of the little progress that the morbid action has made; and if, moreover, we add to this consideration another, viz., that it is principally in the earlier stages of structural alteration that we are able to entertain the most sanguine expectations of a beneficial result to be obtained from the judicious administration of such remedies as the history of our art places within our reach, it must be allowed that there exist well-grounded motives which ought to be regarded as sufficiently strong to impel us to pursue, with ardour and perseverance, that course which a firm conviction of the truth of the precept above referred to would incline us to adopt.

It cannot, then, be disputed that he who has neglected to obtain a correct knowledge of anatomy deserves to be estimated as one who is, in no small degree, unfitted for and incapable of engaging in the practice of our profession; and, although it may be urged in favour of the opposite opinion that many instances can be adduced of men, the most ignorant of anatomy, succeeding in the lucrative exercise of their profession, yet, when we institute more closely an examination into the history of their success, we shall almost invariably be able to show that the individuals in question have been successful only from a combination of fortuitous circumstances, and not from any real and intrinsic merits of their own; that they have frequently obtained credit when they ought to have been disgraced, and, that were we to strike a balance between the number of cases in which they have either done nothing at all, when much good might have been effected by one more competent than themselves, or, where they have been

* Read before the Medical Society of University College, London.

successful (so to speak) in spite of their own endeavours to the contrary, in consequence of the very imperfect and incorrect opinions which they had formed of the nature and seat of the diseases submitted to their judgment and treatment, and those instances in which they could fairly prove, with satisfaction to their own feelings, that the beneficial results were obtained solely from their accurate appreciation of all the circumstances connected with the disease, and by their sound and rational practice, the principles of which they had deduced from, and based upon such previous investigations, the decision would be found, after the whole had been summed up, to be very much against their favour. There are some, no doubt, who are so blissfully ignorant as even to be able to enjoy with comfort and pleasure such a position as this; but there are a much greater number of persons who, although they consider it to be too late to learn and improve it, nevertheless feel their situation to be extremely harassing and insecure, conscious that the occurrence of every case of more than ordinary intricacy or difficulty renders them continually liable to be stripped of the frail and flimsy protection which the ignorance or good-nature of the public has hitherto afforded to them.

On the other hand, however, it must be remembered that it is not sufficient that we possess the most correct and intimate knowledge of the healthy anatomy of the human body, and confine our researches to that alone, but that we ought eagerly to avail ourselves of every opportunity which may be presented to us of investigating what are the deviations from this standard produced by the existence of any diseased action; and also to endeavour to connect, if it be possible, each of these morbid alterations with the particular stage of the progress of the disorder in which it occurs, so that we may be the better empowered to adapt our attempts to afford relief more suitably to the true nature and character of the disease at the particular time that it is subjected to our notice. It so frequently happens that diseased action, when once it has been established, brings into existence additional changes in the condition of the structures submitted to its influence, which changes themselves become, in a secondary manner, the causes of a fresh series of morbid

actions which exasperate, obscure, and even completely mask those that were first produced, so that, unless we are prepared to separate the essential circumstances of the complaint from those which are merely concomitant and adventitious, we render ourselves liable to fall into the grievous error of employing means inadequate to effect the ends proposed (though they might be well adapted to ensure success had they been adopted in another stage), at the same time that we neglect the remedies which are really applicable, and which, were they put into force, would be followed by the happiest results. In numberless examples it could be shown that much more harm has been produced by the too careless and ill-timed exhibition of remedies which are proper for one period or effect of diseased action, but ill suited for any others, than if the case had been altogether left to the unaided but simple efforts of nature.

It would not be easy to adduce an instance of any other disease, the early explanations of which have proved to be more erroneous, or concerning the nature and treatment of which greater differences of opinion have been entertained, at various periods, by the profession, than that of hernial protrusions, as they occur in the inguinal and femoral regions, and which, at the same time, could better serve to exemplify how much may be effected towards the correction and improvement of our ideas of the origin, progress, and cure of a disease by a comparison carefully instituted between the healthy condition of the structures that enter into the composition of the regions in which the affection occurs, and the pathological changes which are produced by its presence.

It is not a very long time since the most cruel and barbarous operations were very frequently practised to procure the radical cure of inguinal herniæ*; and it is only since the anatomy

* "The itinerant operators are dextrous in the separating of these organs, without the spectator's ever perceiving it. They make the ligature of the vessels before they draw the testicle out of the scrotum, and with their little fingers, run below the vessels which they have cut, they force it out, and hide it in their hand, in order to steal it into their purses unseen. We have known one of these operators who fed his dog with nothing but testicles; that animal always lying under the bed, or under the table near his master, waiting for the luscious morsel, with which he was regaled, immediately after its extirpation, unknown to the spectators, who would have sworn that the patient had all his parts."—Dionis's *Chirurgical Operations*, p. 167. 8vo. Lond. 1733.

of the parts concerned in the disease has been better understood, that milder and more judicious plans of treatment have been substituted. Nevertheless, in more modern times, it has frequently happened to some of the best surgeons, to be arrested, in the midst of a delicate operation, by the unexpected appearance of a structure, the resemblance borne by which to another and more important one has led them to conclude the operation to be completed, when really it was but half performed, and thus to leave unfinished an operation which had been commenced under the most favourable auspices; and other cases are not wanting, in which the operation had been performed in all other respects with the greatest skill and éclat, but in which it proved to be of no avail, merely because the operator was not aware, or had forgotten, that the naturally delicate membrane of the peritoneum might become so much altered in its structure, as to constitute an insuperable barrier to the return of the strangulated intestine contained in the hernial sac. In other instances, from an incertitude of the precise situation of the structures, which it was essential to their credit that they should avoid doing any injury to, the most skillful operators have been sometimes compelled, much against their own inclinations, to perform slowly, and step by step, an operation which, upon other occasions, they had frequently performed with the greatest ease and dispatch.

Several opportunities having been presented to me of examining, by dissection, the condition of the investments of the hernial sac, as they are commonly described by anatomical and surgical writers, I avail myself of the present occasion to submit to the notice of the society the alterations from the healthy standard that I observed in these instances.

The *skin* is liable to no other alteration that what depends upon the state of the sac, whether it be distended or empty. In the former case the skin was smooth and thin, while in the latter it is flaccid, and thrown into numerous folds or wrinkles.

The *superficial fascia* was found, in one case of very large scrotal hernia, to be very much thickened, and, at the same time, greatly increased in density, and admitting of being readily divided into three laminæ. In five other instances, the superficial fascia presented

its ordinary appearance; being separable only into two lamellæ, betwixt which were situated the cutaneous vessels which supply superficial coverings of the inguinal region. The external pudic artery lay over the middle of the tumor formed by the hernia after it had emerged from the external abdominal ring, or lower aperture of the inguinal canal, and hence must always be divided by the first incisions in exposing the sac of a complete bubonocoele. The superficial epigastric artery usually runs a little farther towards the anterior superior spinous process of the ilium than the commencement of the neck of the sac, and hence it is very rarely injured by the edge of the knife in an operation for strangulated inguinal hernia, excepting in cases of recent incomplete bubonocoele.

The *external spermatic*, and *intercolumnar fascia*, was considerably increased both in thickness and density in four out of five cases of inguinal hernia. In some of these cases it was twice and even three times thicker than it is naturally. In the fifth case, which was one of very large scrotal hernia, it appeared to be very thin and delicate.

The *intercolumnar fibres*, or bands which serve to connect together the pillars of the external abdominal ring, are pushed upwards and outwards by the hernial sac as it protrudes from the inguinal canal, and are thrust together in such a manner as to form, by their close approximation to each other, a broad and very strong fillet, which limits the farther distension of the ring, and thus communicates a circular form to the aperture when distended by the protrusion through it of a hernial tumor. The intercolumnar fibres become, at the same time that they are displaced upwards and outwards, very much increased in thickness and strength; and to this circumstance is owing that sudden constriction in the bulk of the hernial tumor which, in every case of large scrotal hernia, serves to define with precision the situation of the external inguinal ring.

The *external abdominal ring* is frequently distended to the size of half-a-crown, but it rarely exceeds this size. At the same time, the aperture loses the triangular figure which it naturally possesses.

Such of the fleshy fibres of the *internal oblique muscle* as take their origin

from the middle portion of Poupart's ligament, are more or less displaced by the hernial sac as it descends through the inguinal canal; so that they no longer run, in an oblique direction, downwards and inwards to their attachment to the os pubis, but are forced upwards by the rounded anterior surface of the sac, as it protrudes between the lower edge of the muscle and the spermatic cord, and so are made to form a thick muscular arch, the concave of which embraces about two-thirds of the circumference of the tumor as it lies within the inguinal canal.

The *transversalis muscle* undergoes little or no alteration in its form and appearance by the protrusion of the hernial sac through the internal abdominal ring. In some instances it is encroached upon by the hernial tumor, and its lower edge becomes in consequence rather more arched than ordinary, and the conjoined tendons of the two muscles (the internal oblique and transversalis),—where they descend together to be inserted into the inner extremity of the ileopectineal line of the os pubis, and form the inner part of the posterior wall of the inguinal canal,—are displaced more or less inwards, nearer to the outer edge of the rectus muscle; so that instead of extending an inch, and even more than this, from the edge of the muscle, they do not reach more than a quarter of an inch, and frequently even a less distance from it than this. In the healthy condition of these parts, the conjoined tendons constitute a thin and flat band of fibres; but, when an oblique inguinal hernia has existed for a considerable period, and, at the same time, forms a large protrusion, they are no longer apt to resist, and the tendency which the weight of the contents of the hernial sac has to drag inwards that portion of the posterior wall of the inguinal canal, which is composed of the fascia transversalis and the conjoined tendons, and hence they give way, and are pushed aside in the direction of the mesial line of the body, and so change their extended form for that of a thick, narrow, and strong band.

The *cremaster muscle*, in six cases, was found to be very much altered from its natural and healthy appearance. The fibres of the muscle were enlarged to three or four times their ordinary thickness, and had lost their muscular character, having become pale and

semi-transparent: towards the fundus of the hernial sac, the fibres were so much displaced as to present the figure of an irregular net-work, the meshes of which were of very unequal size and irregular figure. In two instances this investment of the sac of the hernia resembled strongly the pectinated appearance which is observable in the auricular appendages of the heart, but they were also much paler in colour. In another instance, which was also a large scrotal hernia, the cremaster muscle had preserved much of its ordinary appearance towards the upper part of the tumor, although it was there slightly stronger than usual; but towards the fundus of the sac it formed a thick layer of dense cellulo-fibrous tissue, of a uniform surface, and possessed of considerable extensibility. The fibres of the cremaster muscle will be found to form one of the coverings of the sac of a direct or internal inguinal hernia in some cases, but this arrangement is contrary to that which holds in the generality of instances of that affection.

When an internal or direct inguinal hernia commences to be protruded through the middle of the inguinal pouches of the peritoneum—that is to say, in the space between the epigastric artery and the ligamentous remains of the hypogastric artery of the fœtus—the peritoneal sac is seldom, if ever, covered by the conjoined tendons of the internal oblique and transversalis muscles; but when it is protruded through that part of the posterior wall of the inguinal canal which is situated immediately behind the internal abdominal ring, and which corresponds to the innermost of the three inguinal pouches of the peritoneum lining the abdominal parietes, the conjoined tendons will be found covering either the whole of the sac or at least that side which is nearest to the mesial line of the body.

The *fascia transversalis* is, in the majority of cases, but little altered from its usual healthy condition, excepting that the internal abdominal ring is greatly enlarged—principally towards the mesial line—by the protrusion through it of the hernial sac. In one case, however, it presented, over the situation of the neck of the sac, the appearance of a narrow, circumscribed, and unyielding band of condensed cellulo-fibrous tissue, of the thickness of fine packing-twine. In the operation

for strangulated hernia, this covering is frequently mistaken for the peritoneal sac, in consequence of its uniform and delicate appearance and texture.

The *subserous cellular tissue* was found, in several instances, to be a little increased in thickness, but unequally so, from the presence of a number of very small bundles of adipose substance that were deposited here and there in its texture. It frequently appeared to be very vascular where it covered the circumference of the neck of the sac.

In small herniæ, and more especially in cases of femoral hernia, the subserous cellular tissue is frequently so much loaded with fat, that it is at first difficult to distinguish it from the omentum. In several instances of femoral hernia, I have observed it form small tumors, which projected through the inferior aperture of the crural canal (the saphenous opening of the fascia lata); and so striking was its similitude to the omentum, that many mistook it for that structure. In a future stage of the dissections, it was found to be, in each instance, a process from the subserous cellular tissue covering the fundus of the sac of a small incomplete femoral hernia.

The *epigastric artery* is frequently observed to be very much displaced from its customary course, by large and old strangling, oblique, or external inguinal hernia. In such cases, this vessel no longer rules an oblique course from about the centre of the crural arch up towards the umbilicus, but, on the contrary, is carried so far inwards towards the mesial line, that it ascends, after running along the posterior surface of the mesial portion, behind the outer edge of the rectus muscle; and thus the obliquity of the inguinal canal is destroyed, and an instance is afforded of the external inguinal hernia becoming direct, by the destruction of the posterior wall of the inguinal canal; a circumstance which, if overlooked, might lead a surgeon into considerable difficulty, were he, in an operation for a strangulated inguinal hernia, where this change in the relative position of the external and internal rings had been effected, to direct (as is taught to be done by some authorities), while enlarging the stricture existing at the neck of the sac, the cutting edge of the knife towards the linea alba.

The *peritoneum*, which forms the

proper sac of an inguinal or femoral hernia, is seldom found altered from its healthy structure and appearance, excepting at the neck or internal aperture of the sac. In this situation, the peritoneum forms a sharp angular fold, the free border of which projects towards the central axis of the sac. The increased action which is induced in the vessels which nourish this portion of the peritoneum, and the adjacent subserous cellular tissue, and that part of the fascia transversalis which is immediately external to it, by the excitement kept up by the presence of the hernial descent, and frequently by the means employed to maintain it reduced, is followed, after the lapse of a longer or shorter period, by the deposition of new matter around the neck of the sac, which probably, in the first instance, is allied in its nature and properties to coagulable lymph, but which eventually assumes the characters of condensed cellulo-fibrous tissue. The neck of the peritoneal sac is also liable to become greatly thickened, from the changes which occur in it when a hernia has been maintained reduced for a considerable period, as, for example, by the application of a well-adjusted bandage or truss; for in such cases the membrane of the peritoneum, where it passes through the narrow aperture of the internal ring, being no longer distended by the descent of the intestine forming the hernia, falls into loose folds, which present the puckered appearance of the mouth of a purse, the strings of which have been drawn closer together. These folds of the peritoneum soon cohere to each other by their opposing surfaces, and in this manner the neck of the sac is increased in its thickness and density, in the same ratio as the diameter of the aperture is diminished. It is by the co-operation of these several causes, that, in dissecting carefully herniæ of old standing, we so regularly meet with a remarkable thickened and contracted condition of the neck of the sac, and which, so far from presenting its ordinary delicate structure, forms an unyielding band, of a dense cellulo-fibrous, or even a cartilaginous nature, and which too frequently becomes, independently of the surrounding muscles, the seat of the stricture in numerous cases of strangulated hernia. This deposition of new matter around the neck of the hernial sac is always followed by a diminution of the calibre of the

mouth of the sac ; and this circumstance may be satisfactorily explained by reference to the strong and firm structures which are situated around the circumference of the internal abdominal ring, and which prevent its development eccentrically, and to the fact that there appears to exist in tissues of that nature and origin, an inherent tendency to contract the diameter of the circle, the limits of which they surround.

That this morbid alteration of the peritoneum forming the neck of the sac is of very frequent occurrence, my own observation permits me to state ; and it is this condition of the parts which must ever prevent the attempt to relieve the stricture without opening the hernial sac, in operations for strangulated inguinal and femoral hernia, from being generally practicable or successful.

We are mainly indebted to Arnaud, the justly celebrated French surgeon, for the first clear description of the fact that the stricture in strangulated hernia has its seat in the thickened neck of the peritoneal sac ; although, in his own time, the opinion which he held was regarded by his contemporaries as exceedingly erroneous and ill-founded. The late Baron Dupuytren was in the habit of declaring it to be his opinion that the stricture would be found to be situated at the neck of the sac in nine out of ten cases of strangulated hernia ; and there are many other surgeons of equal note, both English and foreign, whose testimony is borne in favour of the same conclusion. A knowledge of this fact is of great use in preventing the more frequent occurrence of those cases in which the strangulated intestines have been reduced into the belly along with the hernial sac, and in which the contents of the sac, still remaining tightly grasped by the contracted orifice of the sac, death followed from a continuation of the strangulation, notwithstanding that (to all external appearance, at least) the hernial protrusion had been returned into the cavity of the belly. Arnaud relates the history of a case which strongly illustrates the beneficial influence which his discovery is capable of, in promoting the more effectual relief of some forms of strangulated hernie. Being sent for to Rouen, he was asked, by a surgeon of that town, how it happened that he was unable to return the strangulated portion of intestine, although he had

performed the operation thirty-six hours previously, and in strict accordance with all the rules of the art thus prescribed. Arnaud requested to be taken to see the patient, before he gave his opinion. On seeing her, he considered that the stricture was seated in the neck of the sac ; "upon which," he says, "the surgeon did me the honour of presenting me with his knife, and obligingly said, *as you have found the fox, it is fit you should kill him.*" Arnaud then divided the sac, which was very deeply situated, and so removed the stricture upon the bowel, and the patient made a quick recovery.

CASE OF

TRANSPOSITION OF THE THORACIC AND ABDOMINAL VISCERA,

Accompanied with an unusual Variety in the Venous System.

BY A. M. McWHINNIE, Esq.

Teacher of Practical Anatomy at St. Bartholomew's Hospital.

[For the Medical Gazette.]

THE subject was a female, about 25 years of age, concerning whose history no particulars could be ascertained. Death was found to have been caused by acute inflammation of the lungs. The body, which was loaded with fat, presented no peculiarity externally.

Attention was first drawn to the fact that there was misplacement of the viscera, from the complete absence of large intestine on the left side of the abdomen. On examining the right iliac fossa, the colon was found to ascend from a very large cæcum, which was rather more elevated than usual, the situation of its appendix vermiformis being reversed. The colon ascended in rather a tortuous course, into the right hypochondrium, whence, instead of crossing the epigastric region, it became folded suddenly upon itself, and descended close to the inner side of the ascending portion, to form a very extended sigmoid flexure. The large intestine being thus confined to the right side of the abdomen, was of about its usual length, and finally pursued its course along the middle line of the sacrum.

The stomach was situated very obliquely ; the larger extremity occupying the right hypochondrium, and the organ

was curved to such an extent that its two orifices were very nearly approximated; the cardiac opening being placed a little to the right of the pyloric.

The duodenum descended first, a little obliquely, towards the right of the vertebral column; then ascended in a line parallel to the other portion, and afterwards passed almost transversely to the left of the spine, so that the jejunum commenced almost in its usual situation. The small intestines were chiefly contained in the left iliac fossa. The superior mesenteric vein was placed in front of the two first and parallel portions of the duodenum, which separated it from the corresponding artery which was behind.

Liver of about the ordinary size; the larger lobe, with which the gall-bladder was connected, placed in the left hypochondrium. The spleen consisted of three distinct portions, connected with the larger extremity of the stomach in the right hypochondrium. Each received one or more large branches from the splenic artery, which divided very near to its origin.

Nothing very remarkable was presented in the appearance of the rest of the abdominal viscera.

Thorax.—The heart occupied rather more the middle line of the chest than ordinarily, the apex pointing to the right side. The situations of the large vessels were completely reversed.

The œsophagus descended to the left of the aorta; the thoracic duct, ascending also on the left of this vessel, formed a curve to terminate at the junction of the right subclavian and internal jugular veins.

The left lung had three lobes.

A remarkable feature in the case is the disposition of the vena cava inferior, which, after being formed by the union of the common iliac veins (in this instance as high as the first lumbar vertebræ), and, receiving the lumbar, renal, spermatic, and phrenic veins, entered the chest through the diaphragm, close to the left of the aortic opening. From this point it continued to ascend parallel with, and to the left of the aorta, and, arriving at a level with the arch of this vessel, curved forward over the left pulmonary vessels to join the vena cava superior.

The thoracic portion of the inferior cava resembled, therefore, the vena azygos; it received the intercostal,

bronchial, and œsophageal branches, and took the same course as this vessel when it exists.

The vena cava hepaticæ united to form a trunk, which entering the chest through the left of the tendinous centre of the diaphragm, terminated separately in the reversed right auricle.

The condition of the spleen is worthy of remark, as having been found imperfect in other instances of transposition of the viscera, and appears to be the only organ in which development has been arrested in these cases.

In the museum of St. Bartholomew's Hospital is preserved the preparation described by Mr. Abernethy in the 83d volume of the *Philosophical Transactions*, where there is a somewhat similar condition of the inferior cava in connexion with the reversed position of the heart. The inferior cava passing through the chest on the right of the aorta, and pursuing the course of the vena azygos, the place of which it supplied, it received also the vena portæ nearly on a level with the renal veins. The veins returning the blood from the liver passed through the central tendon of the diaphragm, and opened separately, as in the above case, into the anterior auricle.

Several instances are recorded, and particularly by Krause, in his *Handbuch der Menschlichen Anatomie*, of variety in the vena cava inferior, and supplying the place of the vena azygos, but apparently unconnected with any abnormal portion of the viscera.

The accompanying sketch, presenting a posterior view, will explain more particularly the unusual arrangement of the vessels, which have been injected, and are preserved in the Anatomical Museum.

Numerous cases of irregular disposition of the viscera have been recorded in this Journal, and particularly in the interesting account communicated by Dr. Watson; many more, however, may be found in the works particularly of the continental writers. My friend, Mr. Curling, has favoured me with the particulars of an example of lateral transposition of the abdominal organs alone, and which he has kindly permitted me to add to the foregoing case—as serving, perhaps, to elucidate the obscure subject of these anomalies.

Henry Beard, aged 40, was received into the London Hospital, October 5,

1839, labouring under symptoms of disease of the heart, with general dropsy. He died October 12th; and on examination of the body, seventeen hours after death, the following appearances were found. The body was muscular and well formed, but generally anasarcaous. There were extensive pleuritic adhesions on the right side of the chest, and about sixteen ounces of serum. The left side contained full three quarts of straw-coloured serum. Both lungs were composed of the usual number of lobes. The heart was in its normal situation on the left side, but very large. The pericardium was somewhat thickened, and contained about two ounces of serum tinged with blood. The left ventricle of the heart was greatly hypertrophied, and there was induration at the base of the aortic valves, but no further disease. Nothing remarkable was observed in respect to the large vessels immediately connected with the heart, and the arrangement of the parts in the posterior mediastinum was quite regular. The cavity of the abdomen contained two quarts of serum, with masses of loose albuminous matter floating in it. All the abdominal viscera were transposed. The stomach was of large size, and situated on the right side of the abdomen; its cardiac orifice, with the great cul-de-sac, being on the right side, and the pyloric orifice on the left. Its direction was somewhat oblique, so as to facilitate the junction of the cardiac orifice with the œsophagus, which entered the abdomen nearly in the usual situation. The pancreatic duct, and ductus communis choledochus, united and opened into the duodenum on the left side. The liver was found on the left side, the gall-bladder being connected to the left and larger lobe. The spleen was rather small, and on the right side; and there were four supernumerary spleens near the principal one. The cæcum, with its appendix, was on the left side; it was not confined to the iliac fossa, but was entirely surrounded with the peritoneum, and quite free and loose. The colon ascended across and in front of the small intestines, towards the right lumbar region, where it made a remarkable turn towards the spine, and then passed across to the left side, between the tenth and eleventh dorsal vertebrae, behind the small intestines, and external to the peritoneal cavity; so that in this part of its course the colon

was uncovered by serous membrane. It afterwards made another turn on reaching the left side corresponding to the sigmoid flexure, and then joined the rectum. The kidneys were large, flabby, and granular, and the right was situated higher up in the abdomen than the left. The chief vessels of the abdomen were also laterally inverted. The arrangement of the iliac and renal arteries and veins corresponded with the position of the abdominal aorta on the right side, and the vena cava on the left. The apertures in the diaphragm for the vena cava and œsophagus were in their usual relative position, though a little nearer the centre than ordinarily.

CASE OF ARM PRESENTATION.

To the Editor of the Medical Gazette.

SIR,

I was requested to attend Mrs. G., in labour of her third child, on Monday forenoon. About half-past 11 o'clock, on examination per vaginam, I found the os uteri considerably dilated. The head was far up, occupying the anterior portion of the os uteri; the arm presented in the posterior. On withdrawing my fingers, a quantity of greenish matter adhered to them, of a very offensive odour. On Saturday night last she first felt the symptoms of labour; she describes the pains as being of a very peculiar character. On going to stool same night, a large cake of a greenish substance passed from the vagina. Since this time the pains have continued more or less, till this morning, when they all but disappeared. At the present stage of labour, from the os uteri not being entirely dilated, I deemed the best line of practice to be non-interference till the parts were fully dilated, and then to insinuate the arm above the head. With this intention I left the patient, giving strict injunction to send for me when the pains returned. From some mismanagement on the part of the attendants, I was not sent for in proper time; for although I arrived about three minutes after being called, the child was born; this was about two in the afternoon. The child had been dead for some time.

This being the first presentation of the kind I had met with, the line of practice that first flashed across my mind was turning; but, upon a more deliberate examination, I was of opinion that it was only necessary to allow the parts to become dilated, and then gently push the arm above the head. This method, of course, I was prevented from adopting, for the reasons above stated. In relating this case to my friend, Mr. J. Black, surgeon, Glasgow, he gave me the history of two cases of a similar nature: one occurred in his own practice, the other in a friend's. Mr. B. having attentively observed the process of nature in his own case, was enabled to state, in consultation with his friend, that turning was unnecessary, and that nature would accomplish the delivery without assist-

ance. The result verified this opinion. Both children were dead in these cases. It is worthy of remark, and ought to be borne in mind by the young accoucheur, that in the event of his not being able to discover what part is presenting with the extremity, he should be on his guard not to attach too much weight to the presence of the meconium, because he may be very easily deceived, the opinion of the present day, so far as I can learn, being this—that the presence of the meconium indicates that the breech is presenting. Suppose I had not been able to satisfy myself in the above case as to whether a hand or foot presented, and none of the other parts within reach, I might have very readily concluded from the presence of the meconium that the breech was presenting, and that the extremity was therefore a foot. The result, in all probability, would have been the conversion of a simple case into an arm presentation, absolutely demanding turning. When the child is dead in utero, every portion of its body loses that tonic force which is present during life; and I can very easily suppose that, independent of great pressure, or the nature of the presentation, the meconium might, from the sphincter ani participating in the general relaxation, be allowed to pass into the vagina; therefore we conceive that its presence ought not to be relied upon as an indication of breech presentation.

If the above case is suitable for your pages, its insertion will much oblige,

Your obedient servant,

JOHN F. KENNEDY.

South Shields, Feb. 19, 1840.

BLEEDING FROM LEECH-BITES.

To the Editor of the Medical Gazette.

SIR,

I SCARCELY know whether the contents of this note are worth publishing, but as I have found the method described accomplish its object remarkably well, it may possibly be of some service to mention it.

About three years ago, when on one occasion leeches were applied to the throat of a child, the bleeding was so profuse and so long continued as to endanger its life. Great difficulty was

experienced in checking the hæmorrhage, from the impossibility of bearing sufficient pressure around the neck. The ordinary means, including powdered nitrate of silver liberally used, were insufficient; it required the constant application of the finger for some time, nor did this tedious expedient succeed until the child had nearly bled to death. In thinking over this case, I determined, should an instance of the kind occur again, to transfix the puncture with a fine needle, and pass around it two or three turns of thread. About a month since, a case of a similar description presented itself. The child had been placed in bed after leeching, where it lay for some time, and the attendants were at last alarmed by finding the little patient deluged in blood. I elevated the punctured skin, and, holding it tightly between the fore-finger and thumb of the left hand, passed through, a little below the base of the bleeding orifice, a very fine sewing-needle, and then wound around it two or three turnings of thread. It appeared to give little pain, probably not more than the bite of the leech; the bleeding was immediately checked, and on removing the needle, three days afterwards, there was no return of hæmorrhage.—I am, sir,

Your obedient servant,

J. C. SPENDER.

Bath, March 17, 1840.

[It may be of use to remind our junior readers of the method of arresting the bleeding of leech-bites here practised, which, however, is nothing new.—ED. MED. GAZ.]

MR. ESTLIN'S SECOND CASE
OF
CYSTICERCUS CELLULOSÆ

Between the Conjunctiva and Sclerotica.

To the Editor of the Medical Gazette.

SIR,

IN a former number of your publication (MED. GAZ. for Aug. 25, 1838, p. 839,) I gave an account, accompanied by a drawing, of the hydatid *Cysticercus Cellulosæ*, which I unexpectedly discovered on puncturing a small tumor upon the sclerotica of a child's eye. A few

weeks ago another child was brought to the Dispensary for the cure of diseases of the eyes, with a tumor very similar in appearance to that before described: The patient was an infant of about 16 months old, named William Symonds; the tumor, semi-transparent, and about as large as a moderate sized English currant, was situated, as in the former case, at the inner canthus of the right eye, above the caruncle, between the tendinous expansions of the insertion of the attollens and abducens muscles. It could only be seen when the eye was directed obliquely outwards and downwards. The conjunctival portion of the membrane covering the tumor externally was very vascular, and much thickened, and the tumor itself was tense, and not very elastic: in order to puncture it, it required considerable pressure with the finger of the left hand to retain it in a situation where it was completely visible.

The exact resemblance of this little swelling to that which I described in your former volume, prepared me for expecting it to contain a similar parasite; and I consequently carefully watched it while making an opening into the sac. As soon as a puncture was made, some viscous, and rather purulent fluid, escaped, and the hydatid, in a collapsed state, slowly came out, looking like a very white or solid portion of membrane about one-tenth of an inch in diameter. On being put into water, the cyst expanded itself into a beautifully transparent membrane, strongly contrasted with the solid opaque head and neck. With a lens of an inch focal length, the four sucking discs surrounding that at the extremity of the head which contained the circle of hooks, were perfectly distinct. A very exact magnified representation of the head of this hydatid, in an uncompressed state, may be seen in the engraving illustrative of Mr. Curling's lectures on the Entozoa, in the MED. GAZETTE for Jan. 13, 1838, page 601, excepting that in my specimen the depression or aperture in the absorbing discs are larger, giving those protuberances a more cup-like form. Upon gently compressing the cysticercus between two pieces of glass, and viewing it as a transparent object by transmitted light with an achromatic microscope, the appearance was precisely that figured in the drawing accompanying my former paper, the small oval bodies

upon the head and neck, there described, being very apparent in the new specimen. Scarcely any mark remains upon the eye of the child from whom the hydatid was extracted.

I am induced to record this second case which has fallen under my notice with the view of calling the attention of surgeons, and particularly of those who have the care of ophthalmic institutions, to the vesicular tumors which are occasionally found upon the sclerotica, as I cannot but suppose that they oftener contain hydatids than is generally conjectured to be the case, though I have not heard of their being so situated in any other instances than in those I have detailed.—I am, sir,

Your obedient servant,

J. B. ESTLIN.

Bristol, March 19th, 1840.

P.S.—Since writing the above, I have read, in the *Gazette Medicale de Paris* (for Oct. 8th, 1839, p. 636, in a notice of the articles in the German medical periodicals,) a case where a cysticerous cellulosa was found by Dr. Hoering in a conjunctival tumor that had followed a contusion of the eye. Reference is made to two other German publications, where this parasite is described as having been found beneath the conjunctiva, but no particulars are given, and the circumstance is mentioned as one of rare occurrence.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

The Theory of Horticulture; or an attempt to explain the principal Operations of Gardening upon Physiolo- gical Principles. By JOHN LINDLEY, Ph. D. F.R.S. Vice-Secretary to the Horticultural Society of London, and Professor of Botany in University College. 1 vol. 8vo. London, 1840.

A History of British Ferns. By EDWARD NEWMAN, F.L.S. 1 vol. 8vo. London, 1840.

THE admitted importance of every thing which bears upon the production of food, would justify us in noticing here the former of the works, the title of which is given above, even if the physiological interest of its contents did not demand a

careful investigation into its merits. The close connection between a defective supply of nourishment and the appearance of disease entitle every plan for the augmentation or improvement of the chief articles of diet to the consideration of the physician, as well as of the philanthropist and political economist. Dr. Parry conferred benefits on the human race by his contributions to the Transactions of the Agricultural Society of Bath, quite as important to their well-being, as by his elucidations of disease in the Elements of Pathology; and Dr. Lindley is no less a friend to mankind, in laying before the public a portion of his extensive knowledge of vegetable physics, as applied to the art of gardening. Those who may have no means of applying his judicious rules to practice in their own fields or gardens, may peruse, with much profit, this succinct, but lucid, exposition of the principles of horticulture. It is impossible to read the successive chapters of this work, without admiring the variety yet exactness of the knowledge brought to bear upon the subject; or failing to perceive how analogous many of the habits of vegetables are to those of animals. If all nature be a school, in which something is constantly to be learnt, the advantage of an able expositor of the phenomena must be obvious; and the individual who aims at improving the constitution of the human kind, may receive most valuable lessons from the habitudes of plants in crossings and hybrids. One instance will be sufficient:—Speaking of the late Mr. Knight's efforts to improve fruits, Dr. Lindley states, “he found that the most perfect and vigorous progeny was obtained, of plants as well as of animals, when the male and female parents were not closely related to each other.”

Disregarded as this law is in forming intermarriages, its truth cannot be too extensively enforced; and a most striking confirmation of it is to be found in the history of the families in which deaf and dumb children are born. In the greater number of cases it will be found, that the parents were related before marriage; such, at least, was the result of an inquiry into the parentage of the children in the Asylum for the Deaf and Dumb a few years ago.

But, desisting from special inferences to be drawn from the laws explained in

this work, we would revert to their connection with that subject of universal import—the increase of the quantity of food. If it be true, as maintained by the political economists, “that he is a benefactor to his race, who makes two blades of grass grow where only one grew before,” what must he be who makes ten? Now, a greater augmentation than this has been effected in some districts which were most unpromising at first. In the ninth report of the Glengkiln Society (see *Quarterly Journal of Agriculture*, for Dec. 1839) it is stated, “the proper succession of crops has been carefully studied; and, in the opinion of Mr. Dudgeon, since 1784, *by a mere change in the rotation*, the produce has, in many places, been increased ten-fold;” and more than even this may be hoped for from a similar cause—attention to vegetable physiology. We owe our best thanks to Dr. Lindley, for providing so valuable a manual to all those who wish to understand the subject.

We have left ourselves but little room to notice the other work on our list. This, however, is the less necessary, as the volume will recommend itself to all those who bestow even a casual glance upon it. It is an attempt on the part of Mr. Newman, not only to describe and delineate all the British ferns, but to reform their nomenclature. That in the first of these objects he has been most successful, needs no proof: difference of opinion will always exist, relative to the systematic part, and Mr. Newman is as well entitled to entertain his views as other classifiers. It is prefaced by some judicious observations and rules for the culture of ferns; and as it is only by long and close observation of the varieties of ferns, under cultivation, that the claims of some to be retained as species, or designated varieties, can be settled, these hints must be very valuable.

It is scarcely requisite to add, that the work is brought out in a style which commends it to persons of taste, as well as to the student; for, besides the actual subjects of the treatise, it is everywhere ornamented with vignettes and fragments of scenery, or buildings, where ferns display themselves,

And along with many “a flower,
Shew Flora’s triumph o’er the falling tower.”

MEDICAL GAZETTE.

Friday, March 28, 1840.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”
CICERO.

LONDON, ANCIENT AND MODERN.

IN an essay on the progress of London, one of the most interesting topics is the advancement of the healing art in its several branches. Dr. Bureaud-Riofrey, whose work we mentioned in our last article*, has dedicated some pages to this subject; but it deserves a volume. In early times the priest and the physician were one. He whose religious rank attracted the respect of the people was consulted in other cases where especial intellect or education was requisite; so that in primitive ages the same clear head which interpreted the decrees of heaven, and framed laws for the guidance of society, was supposed to suffice for the details of physic and architecture, and every art that demanded learning and ingenuity. As time wore on, a separation took place, and, contrary to the opinion of many medical declaimers, we even find the subdivisions of our profession among the ancients. Thus, in the third book of Herodotus, Cyrus sends to Amasis for the best *ἱηπρος ὀφθαλμων*, or eye-doctor, in Egypt: in Celsus we read not only of surgeons, such as Gorgias, Heron, and Meges, *chirurgorum eruditissimus*, but of Euelpides, a celebrated *ocularius medicus*: the Anthologia makes mention of Sosander, a horse-doctor; and in the Hippocratic oath the young physician promises that he will not cut for the stone, but will leave it to those skilled in the art. Still, there is no doubt that even in those bright periods, the union of these branches was, at least, as com-

* Londres, Ancien et Moderne, &c.

mon as the distinction ; and, in the dark ages which intervened between the fall of the Roman Empire and the revival of literature, it would have been vain to seek for a Meges or a Euelpides. It is probable that during this dim interval the number of lay practitioners was very small, and that the refinement of subdivisions was almost unknown till the council of Tours, in 1163, prohibited churchmen from performing bloody operations, and thus, in a manner, offered a premium for lay surgery. The separation between physic and divinity seems to have advanced pretty far in the 15th century. Menage, after observing that physicians were formerly ecclesiastics, informs us that, in 1452, the Cardinal d'Etouteville, during his nunciature in France, obtained permission for them to marry. The doctor of physic, too, described by Chaucer some twenty or thirty years afterwards, is clearly not a clergyman ; yet the separation was by no means complete in that century ; and the reader who has a moderate acquaintance with English history, and knows how constantly the highest dignitaries of the church held the office of Lord Chancellor, will not be surprised to learn that Linacre, the founder of the College of Physicians, was a priest. Nor will he be astonished that Henry VIII. practised physic, and drew up receipts for unguents, waters, and cataplasms. The fact is, that Henry was a complete scholar, according to the fashion of the age, armed against every disputant, and qualified to thunder forth theology against Luther, or Lambert, the school-master, one day, and discuss the *strictum* and the *laxum* with a medical professor the next.

A delightful point in the practice of the royal physician was, that he gave fees to his patients instead of receiving them. Thus, in his book of accounts, we find such entries as these :—

“ July 28, pd. to a poor child, the which the king's grace heled at Windsor, vijs. vjd.

Sept. 11, to two pooer folks that were heled of their sickness, xvsh.

Sept. 18, to two pooer folke that the king's grace heled, xvsh*.”

Dr. Bureaud-Riofrey, after observing that Mary and Elizabeth proposed remedies against the plague, adds, that the latter was so jealous of all the prerogatives of the crown, that she caused persons affected with scrofula to be presented to her, whom she cured, as her courtiers said, by the touch of her royal hand.

This touching for the king's evil, however, was not peculiar to Elizabeth, but was practised, we believe, by every English sovereign from Edward the Confessor to Queen Anne ; the last had the honour of touching Dr. Johnson. Nor do we think that Elizabeth *caused* the patients to be presented to her ; the parents were too happy to bring them.

The medical condition of England about this time must have been bad enough. For just as there was an interval between the abolition of the monasteries and the passing of the 43d of Elizabeth,—during which the poor were driven into irrepressible rebellion, through the want of the relief previously afforded by the convents,—so there seems to have been a similar interregnum between the decline of the old system of clerical medicine, and the establishment of the medical polity of the last 150 years.

It must be allowed, indeed, though the declaration seems a paradox, that in uncultivated ages, although there is more death, there is less disease. Human life is shorter ; plague, dysentery, and sweating-sickness, depopulate whole provinces, but the slight ailments, which make up the bulk of medical practice, are less frequent, and less regarded. In former times, the well-housed, well-

* Life of Linacre, by Dr. J. N. Johnson.

fed classes, who are able to lie by, as the phrase is, on every slight attack of disease, bore a far smaller ratio to the mass of the community; and the artisan, yeoman, or petty dealer, overlooked slight maladies, or trusted to domestic remedies. But when these did not suffice, what practitioners could London consult in the 16th and 17th centuries? The only legal advice (excepting in surgical and obstetrical cases) was that of members of the College of Physicians. Their fee of £1, was of itself a prohibition to all but the rich; and physicians were so few in number, that they could scarcely have sufficed for the service of the Court, the Parliament, and a handful of opulent citizens. Thus, we learn that, on one occasion, in the reign of Queen Mary, the *comitia* of the College could not be held at the appointed time, as the Fellows were all occupied with attending cases of epidemic ague.

It is clear that the necessities of the nation could not allow such a state of things to last; and, accordingly, in spite of censures and prosecutions, surgeons, apothecaries, midwives, herbalists, farriers, and astrologers, broke in upon the golden monopoly. The clergy, of course, practised to a considerable extent; and the Lady Bountifuls brought their plague-water and surfeit-water into the national stock of physic. One generally pictures a Lady Bountiful, if not absolutely withered, at least no longer in her prime youth; but the old romances, apparently founded on nature, represent young women as practising physic and surgery. The instance of Angelica who stanches the wound of Medoro with some vulnerary herb, (the poet does not know whether it was *dittamo* [dictamnus] or *panacea*) will occur to our readers*.

In such an instance as this we may well say, with Dr. Bureaud-Riofrey,

“On guérissait des maladies par invocation, à l’aide de charmes.”

With the progress of medicine and of society, female practice has much declined, though no less a man than Dr. Gooch wished to see it revived.

On the whole it is difficult to avoid coming to the conclusion that, until the beginning of the 17th century, or even a later period, considerable towns must have been as ill provided with medical counsel as the small villages of the present day.

After Roger Bacon, the next English physician mentioned is Gilbert, of whom he says that he lived in the 15th century. This is obviously a mistake, as John a Gaddesden, his pupil, was physician to Edward II., and therefore lived in the beginning of the 14th. Dr. Bureaud-Riofrey makes very merry with John a Gaddesden’s famous treatise, the *Rosa Anglicana*. His method of curing small-pox by wrapping up the patient in scarlet cloth; the powder of a roasted frog hung round the neck to stop hæmorrhage; and crow’s eggs as a remedy for epilepsy, are unquestionably points more curious than commendable. Yet we have little doubt that the student who had the courage to wade through *Rosa Anglicana*, would find matter of a better kind. The reader who has been taught to think that every thing worth knowing in physic has been discovered within the last forty or fifty years, will often be surprised, on taking up some old treatise, to find how much was known in the dark or twilight ages*.

The Doctor goes so far as to say that

* In the *Practica Usualis*, a black-letter repository of antique practice, we find mention of the *cacia* pills, so often talked of by the lower orders. The following is the passage (we spare our readers the abbreviations):—“*Digesta materia purgetur cum pillulis cochiis, cum quibus quasi omnes conveniunt.*”

We will take this opportunity of observing, that the treatment of erysipelas by scarification, the invention of which was contested some years ago by Mr. Copland Hutchison and Mr. Lawrence, is to be found in Freind:—

“In inflammatory cases, and in erysipelas particularly, it is often seen by experience that

medicine was in the hands of empirics and women until the time of Henry the Eighth. This is, perhaps, too broadly stated; but he goes still farther when he adds, a few lines afterwards, "*dans un état de choses aussi affligeant pendant le XIV^e. XV^e. XVI^e. et XVII^e. siècles,*" &c. In the sixteenth and seventeenth centuries, illuminated by Linaere and Caius, by Harvey and Sydenham, the signs of progress were cheering, though the medical condition of the country was still bad. It is true that too large a portion of the population lacked regular advice; but the practice of physic was making rapid strides: the people were not wholly in the hands of empirics and women, and though the surgeons and apothecaries of those ages might not be all that could be desired, they did not cure "*par invocation, à l'aide de charmes.*"

Apothecary practice in a quiet way, founded principally on the treasured prescriptions of physicians, must have begun at an early period. We read, that when Harvey fell into disrepute as a practical man, through his physiological researches, there were apothecaries who would not give threepence for one of his bills; the bills or prescriptions of the physician being hoarded to form a practical system of medicine for the apothecary. The same method is probably pursued by the druggists of the present day. It is needless to trace the gradual rise of the apothecary, until, by the decision of the House of Lords, in 1721, he was made the physician of the middle classes, and an aching void in the fabric of English society was reputably filled up.

The barber-surgeon of the middle ages gradually abandoned the servile

scarifying upon the part, when the membranes are loaded and thickened, will remove the inflammation in a very sudden and surprising manner."—Hist. of Physic, by J. Freind, M.D. vol. i. p. 76.

The revival of the practice is undoubtedly due to Mr. Copland Hutchison.

part of his double occupation; and, throwing off his allegiance to the physician, became, like the apothecary, his formidable enemy. The reason for these successful rebellions we have already given in the present essay, as well on former occasions. How could physicians expect to retain the monopoly of practice, when their fee was equal to half a year's rent of a large mansion?

The progressive cheapness of advice has also been accompanied by a corresponding cheapness of medicine; so that medical treatment is now brought within the reach of a greater proportion of the community than at any former period. Let us hope that this is an illustration of the axiom that it is the effect of civilization to make good things cheap.

In consequence of the bad ventilation and drainage of ancient London, and the unwholesome modes of life of its inhabitants—perhaps also from the lack of good medical advice—the deaths were more numerous than the births; so that the population was kept up and increased by immigrants. Graunt tells us how rapidly any depopulation was repaired, in a passage which looks as if he thought more of money than of men:—"I say it followeth, that let the mortality be what it will, the city repairs its loss of inhabitants within two years; which observation lessens the objection made against the value of houses in London, as if they were liable to great prejudice through the loss of inhabitants by the plague*."

Dr. Bureaud-Riofrey has fallen into a singular inconsistency on the subject of population in England; for, at page 38, he says that in 1558 intermittent fevers were so common and so destructive, that hands could not be found to gather in the harvest; while, at page 90, he tells us that in 1558 the popula-

* Observations on the Bills of Mortality, p. 36, edit. 1661.

tion was so great, and its increase caused so much apprehension, that the poor were not allowed to marry before thirty.

The progress of urban improvement in London, from the first bridge built over the river to the days of gas-lighting and the Thames Tunnel, deserves its historian, but cannot be treated of at the end of an article.

ON THE NERVES OF THE GRAVID UTERUS.

BY ROBERT LEE, M.D. F.R.S.

[Abstract of a paper read at the Royal Society.]

THE author, while dissecting a gravid uterus of seven months, on the 8th of April, 1838, observed the trunk of a large nerve proceeding upwards from the cervix to the body of that organ along with the right uterine vein, and sending off branches to the posterior surface of the uterus; some of which accompanied the vein, and others appeared to be inserted into the peritoneum. A broad band, resembling a plexus of nerves, was seen extending across the posterior surface of the uterus, and covering the nerve about midway from the fundus to the cervix. On the left side, a large plexus of nerves was seen, surrounding the uterine veins at the place where they were about to enter the hypogastric vein. From this plexus three large trunks of nerves were seen accompanying the uterine vein, which increased in size as they ascended to the fundus uteri. From the nerve situated on the posterior surface of the vein, numerous filaments passed off towards the mesial line, as on the right side; some following the smaller veins on the posterior surface of the uterus, and others becoming intimately adherent to the peritoneum. The largest of the nerves which accompanied the uterine vein was traced as high as the part where the Fallopian tube enters the uterus; and there it divided into numerous filaments which plunged deep into the muscular coat of the uterus along with the vein. A large fasciculated band, like a plexus of nerves, was also seen on the left side under the peritoneum, crossing the body of the uterus; and several branches, apparently nervous, proceeding from this band, were distinctly continuous with some of the smaller branches of nerves accompanying the uterine veins. The preparation of the parts was placed in the Museum of St. George's Hospital, on the 1st of October,

1838; and several anatomists who examined it were of opinion that they were absorbents accompanying the uterine veins, and tendinous fibres spread across the posterior surface.

Dr. Lee availed himself of another opportunity which presented itself on the 18th Dec. of the same year, of examining a gravid uterus in the sixth month of pregnancy, which had the spermatic, hypogastric, and sacral nerves remaining connected with it; and during the last ten months, he has been diligently occupied in tracing the nerves of this uterus. He believes that he has ascertained that the principal trunks of the hypogastric nerves accompany, not the arteries of the uterus, as all anatomists have presented, but the veins; that these nerves become greatly enlarged during pregnancy; and that their branches are actually incorporated, or coalesce with the branches of the four great fasciculated bands on the anterior and posterior surface of the uterus, bearing a striking resemblance to ganglionic plexuses of nerves, and sending numerous branches to the muscular coat of the uterus.

The author gives the following description of the nerves of the gravid uterus in the sixth month, and of these fasciculated bands as displayed in the dissection.

Behind the uterus, the aortic plexus divides into two portions, to form the right and left hypogastric plexuses. These plexuses, after an intimate union with the nerves accompanying the ureters, descend to the neck of the uterus, upper part of the vagina, and contiguous parts of the bladder and rectum, where they are joined by branches from the third and fourth sacral nerves. The left hypogastric plexus, about two inches below the aortic plexus, sends off a large branch, which passes on the inside of the ureter to the superior uterine vein, where it is about to terminate in the hypogastric vein. Here the nerve suddenly expands, becomes broad and thin, and passes into a great plexus of nerves, which completely encircles the vein. This plexus, surrounding the uterine vein, is joined below by two large branches, which proceed from the hypogastric plexus, nearer the vagina, and lower down, and from which branches pass on the outside of the ureter. From the upper part of this plexus, surrounding the uterine vein near its termination, three large trunks of nerves proceed upwards with the vein to the superior part of the uterus, and enlarge as they ascend. The posterior branch of these hypogastric nerves sends off in its course smaller branches, which accompany the ramifications of the uterine vein on the posterior surface of the uterus. Passing upwards beyond the junction of the

spermatic with the uterine vein, and running between the peritoneum and the left posterior fasciculated band, it spreads out into a web of thin broad branches and slender nervous filaments, some of which are inserted into the peritoneum, and others follow the vein to the fundus uteri, which they completely surround as the vein passes down into the muscular coat of the uterus.

Some of the branches of this nerve, near the fundus uteri, are distributed to the muscular coat, but these are small and few in number.

The middle and anterior branches of the hypogastric nerves adhere closely to the uterine vein as they ascend, and form around it several plexuses, which completely invest the vessel. From these plexuses branches are sent off to the anterior surface of the uterus, some of which, in an arborescent form, follow the trunk and branches of the uterine artery. These two hypogastric nerves ascend, and closely unite with the left posterior fasciculated band.

On the left side of the uterus this band arises near the mesial line, on the back of the uterus, midway between the fundus and cervix, from a mass of fibres, which adhere so firmly both to the perineum and muscular coat, that it is difficult precisely to determine their arrangement. From these fibres the band proceeds across the uterus, in the form of a thin web, to the point where the spermatic vein is leaving the uterus. After closely uniting with the hypogastric nerves, this band proceeds outwards to the round ligament, becoming less firmly adherent to the peritoneum, where it unites with the left anterior band and spreads out into a great web, under the peritoneum. The left posterior band it loosely attached, through its whole course, to the subjacent muscular coat by soft cellular membrane.

The spermatic nerves on the left side pass down to the ovarium with the spermatic artery, and first give off several branches to the corpus fimbriatum. A few small branches are then sent into the outer end of the ovary. The spermatic nerves afterwards leave the artery, and proceed with the veins to the uterus, where they firmly unite to the outer extremity of the left posterior band; and after the junction of this band with the prolongations of the anterior band under the round ligament, numerous small delicate filaments, apparently nervous, are sent to the base of the ovarium.

On the right side of the uterus, the author finds that the distribution of the hypogastric and spermatic nerves does not essentially differ from that now described as seen on the left side. The form and

situation of the right posterior band is, he states, much more clearly seen than on the left side, and presents the appearance of a white pearly fasciculated membrane about a quarter of an inch in breadth, proceeding from the mesial line at right angles to the hypogastric nerves, across the body of the uterus, to the round ligament, where it unites with the anterior band. Numerous branches, strikingly resembling the branches of nerves, are sent off from the upper and lower edges of this band, and from its posterior surface to the muscular coat of the uterus. An extensive and intimate union at various points is distinctly perceptible between these branches sent off from the band and the branches of the hypogastric nerves. On the anterior and upper part of the neck of the uterus, there is a great mass of reddish-coloured fibres, firmly interlaced together, resembling a ganglion of nerves, into which numerous large branches of the hypogastric nerves on both sides enter, and to which they firmly adhere. From the upper part of this fibrous substance there passes up, over the whole anterior surface of the uterus, a thin band of firm white fasciculated fibres, prolongations of which extend to the round ligaments,—into which, and into the posterior band, they are continued by numerous filaments, like those of nerves. From the posterior surface of this great band, numerous branches, also apparently nervous, can be traced to a considerable depth through the muscular coat of the uterus.

The author concludes his paper with the following remark, and a short historical account of the progress of discovery on the subject of the nerves of the uterus:—

“From the form, colour, and general appearance of these fasciculated bands, and the resemblance they bear to ganglionic plexuses of nerves, and from their branches actually coalescing with the hypogastric and spermatic nerves, I was induced to conclude, on first discovering them, that they were nervous plexuses, and constituted the special nervous system of the uterus. The recent examination, however, of the gravid uterus of some of the lower animals, in which I have found a structure similar to those bands in large quantity under the peritoneum, has left me in considerable doubt as to the nature of these bands, and until further investigations have been made, I shall not venture to pronounce a positive opinion respecting them.”

The description of the nerves of the uterus contained in Professor Tiedemann's splendid work, the author adds, is usually referred to by anatomical writers as the most accurate and complete which has ever been given. Professor Tiedemann has represented the spermatic nerves as

being distributed chiefly to the ovarium; and the hypogastric as invariably accompanying the trunk and branches of the uterine arteries, along the sides of the uterus, -- dividing into smaller branches, and quickly disappearing in the muscular coat of the uterus. He has made no mention of the large nervous trunks on both sides of the uterus, which accompany the uterine veins; nor has he noticed fasciculated transverse bands on the anterior and posterior surfaces of the uterus, connected with the hypogastric and spermatic nerves.

MEDICO-CHEMICAL HISTORY OF MILK.

By DR. BIRD.

(From Sir A. Cooper's Work on the Mamma.)

MILK is a white opaque fluid, possessing a bland, sweetish taste, secreted by certain glands in Mammalia, and designed for the nourishment of their offspring.

The specific gravity of cow's milk, which may be assumed as the type of the different varieties of this secretion, is about 1.030. This, it is obvious, is far from being constant, as it must necessarily vary with the amount of solid matters present, and which depend upon the health, vigour, age and nourishment of the animal, as well as on the time that has elapsed since parturition, and other causes.

Under the microscope, myriads of extremely minute globules are seen floating in milk; these, on account of their extreme minuteness, appear black at their edges, and with a magnifying power of 100, the largest of them does not exceed in diameter, according to Raspail, .00039 inches. On the addition of a drop of solution of potass, the globules are seen to vanish, and a limpid fluid is left.

As the opacity of milk depends on its holding in diffusion myriads of opaque globules, Sir A. Cooper has by straining it repeatedly through a filter sufficiently fine, separated the opaque particles. On submitting this to the test of experiment, I have also found it to succeed most perfectly, a nearly limpid fluid resulting after the milk had been repeatedly filtered.

The simplest mode of regarding milk is that of an emulsion, formed by the intimate mixture of a fatty matter termed *butter*, with an albuminous constituent, called in chemical language, *casein*. The intimacy of the mixture is doubtless increased by the presence of sugar of milk, as saccharine substances are well known to possess the property of forming imperfect emulsions with oils.

Cow's milk contains on an average about 10 or 11 per cent. of solid matter, made up of organic and saline constituents.

When milk is permitted to repose for a few hours a large proportion of its oily constituents, mixed with some of its caseous matter, slowly separates from the mass of fluid, and being of lower specific gravity than the latter, rises and forms an opaque layer on its surface. This lighter portion is termed *cream*, and the milk from which it is thus separated is popularly termed *skimmed milk*, because the cream is skimmed off, for the purpose of being converted into butter. The specific gravity of the cream is on an average 1.0244, and that of skimmed milk 1.0348, the greater gravity of the latter affording a sufficient explanation of the phenomenon of the cream floating on its surface.

If the milk from which the cream has been thus separated, be left to itself, it sooner or later undergoes a spontaneous change, some free lactic acid becoming developed, and the albuminous constituent, *casein*, separates in large white coagula. The development of lactic acid, in all probability, arising from the reaction of caseous matter on the saccholactin, or sugar of milk, as lately pointed out by M. Fremy. This always takes place with greater rapidity in warm than in cold weather, and is hastened during an electric state of the atmosphere, as during a tempest. The addition of a small quantity of any free acid, or of the well-known *rennet*, greatly facilitates this change and consequently coagulation of the caseous matter. The serous fluid from which the *casein* or curd has been thus separated, is popularly termed *whey*.

When whey is submitted to evaporation so as to free it from a large proportion of water, it on cooling crystallizes in small brownish grains; constituting sugar of milk. In Switzerland a very large quantity of this sugar is procured from the whey left after separating the curd in the process of cheese making, and is used by the peasants for all the purposes to which cane sugar is applied in this country.

Sugar of milk consists of—

Carbon	45.94
Hydrogen	6.00
Oxygen	48.06
	<hr/> 100.00

It is generally stated to be incapable of undergoing the vinous fermentation, although an alcoholic fluid termed *koumiss*, has been long prepared by the Tartars from mare's milk. It is now, however, placed by the researches of Hess, (POGGENDORFF, *Annalen*. 21., 194,) beyond a doubt, that

sugar of milk is capable of being converted into alcohol by fermentation, although not with so much readiness as cane or grape-sugar.

A layer of cream formed on the surface of milk by repose is by no means homogeneous, for on carefully examining it, two distinct portions, not, however, separated by any very evident line of demarcation, may be made out; of these the uppermost is richest in butter, and the lowest in caseous matter. The average proportion of cream separated from milk by repose is about one-eighth, but this varies considerably.

When cream is submitted to mechanical agitation, as in a churn, it separates into two portions, the one being a soft fatty substance of an agreeable odour, constituting the well-known butter; the other is a more serous fluid, holding some casein, some sugar, and saline matters in solution, and termed butter-milk, the *petit-lait* of the French. Butter generally contains about one-sixth of its weight of caseous and other matters mechanically mixed with it; these by careful fusion become separated, and then the butter may be kept for a long time without becoming rancid.

After butter has been carefully fused, filtered through paper whilst melted, and well washed with water, it is nearly pure; in this state, 100 parts of hot alcohol dissolve 3·46 parts of it. Butter thus purified, contains, like all other fats, *oleine* and *stearine*, with the addition of a third fatty ingredient peculiar to butter, and hence named *butyrine*.

Anything like a quantitative analysis of milk can, it is obvious, be considered in no other light than that of affording an approximation to the average proportion of its principal ingredients. The following are the results of the analysis of Berzelius.

1000 parts of *skimmed milk*, of specific gravity 1·033, contained—

Water	928·75
Caseous matter with traces of butter	28·00
Sugar of milk (saccholactin)...	35·00
Lactic (acetic) acid, acetate of potass, and traces of a salt of iron	6·00
Hydrochlorate and phosphate of potass.	1·95
Phosphate of iron	0·05
1000 parts of <i>cream</i> , of specific gravity 1·024, consisted of	
Butter	45
Caseous matter	35
Sugar of milk and saline ingredients	44
Water (<i>butter milk</i> ?)	876

By incineration, caseous matter leaves above 6·5 per cent of ashes, consisting chiefly of phosphate of lime.

The caseous matter, or casein of milk, constitutes the basis of cheese: it may be considered as bearing the same relation to milk, that the albumen does to blood.

It is, indeed more than probable, that casein is but a modification of ordinary albumen, and hence may, in a physiological sense, be considered as the albuminous principle of milk. Casein is precipitated from its solutions as in milk, by the addition of acids, which indeed appear to combine with it, for by separating them by a very simple chemical process from the coagula, the casein once more becomes soluble in water. A familiar example of the coagulation of casein by an acid is met with, in the vomiting of curdled milk by suckling infants; the coagulating agent in these cases, is probably hydrochloric acid, which from the researches of Dr. Prout and Leopold Gmelin, appears to be constantly present in the stomach. The rationale of the disappearance of this disagreeable symptom, on the administration of a few grains of chalk or magnesia, is hence sufficiently obvious.

Casein, when rendered as pure as possible, consists, according to the analyses of Gay Lussac and Thenard, and Berard, of—

	Carbon.	Oxygen.	Hydrogen.	Nitrogen.
Gay-Lussac and Thenard	59·78	11·41	7·43	21·38
Berard.....	60·07	11·41	699	21·51

Damp casein, when set aside in a warm place, rapidly undergoes putrefactive fermentation, and a complex mass results, consisting, according to Prout, of two substances, termed caseic acid and caseous oxide, or according to Braconnot, chiefly of a matter termed aposepodine.

Milk drawn shortly after parturition, differs in its physical and chemical character from milk drawn at a more distant period. This variety is termed *colostrum*; that of the cow is yellow, mucilaginous, and occasionally mixed with blood; it

contains but mere traces of butter or other fat, and appears to contain albumen as one of its ingredients, as by exposure to heat, it completely solidifies, like so much serum of blood. The specific gravity of the *colostrum* of the cow is about 1·072. This secretion does not turn sour like milk, but readily putrefies; and in three or four days after the birth of the calf, is replaced by the ordinary lactal secretion.

The *colostrum* of the cow, ass, and goat, has been submitted to examination very lately by MM. Chevalier and Henry.

They state the property possessed by this secretion of undergoing coagulation by heat, although they have not mentioned albumen among its ingredients. It is probable that it was confounded with the mucous matter, stated by these gentlemen to be present in the fluid. The following is the result of their analysis of the colostrum of the cow :—

Casein	15.07
Mucous matter.....	2.00
Saccholactin or sugar of milk	?
Butter	2.60
Water	80.33
	<hr/>
	100.00

On taking a retrospective glance at the above remarks on the composition of cow's milk, which I have taken as a standard or type of this class of secretions, we cannot help being struck with the peculiar manner in which the different component parts appear to be arranged, for the more ready nourishment of the new-born animal. Milk may be physiologically regarded as made up of three classes of ingredients, the first containing those which resemble vegetable secretions in the absence of nitrogen; the second including those which contain abundance of nitrogen, and consequently afford a proper pabulum for the growth of the young animal; the third class containing those ingredients which in the present state of chemical physiology we have no safe grounds for supposing are *digested*, or their elements rearranged by vital chemistry, and hence differ from the first two classes in being rather *appropriated* by the vital influence of the infant animal, than assimilated to form such combinations.

- A. *Ingredients of milk in which nitrogen is absent.* Sugar of milk, fatty matters.
- B. *Ingredients of milk in which nitrogen is present.* Caseous matter.
- C. *Inorganic, or saline ingredients.* Salts of potass, soda, lime, and iron.

The latter class contains those earthy salts which constitute the chief ingredients in osseous structures; and all being dissolved in, or diffused through, abundance of water, become fitted to pass or drain through the minutest vascular tissues.

A CASE OF TWINS,

WHERE ONE HAD BEEN LONG DEAD.

By Dr. C. Th. v. SIEBOLD, of Dantzic.

AN unmarried woman, aged 25, pregnant for the second time, was delivered of a stout boy at the full time, at 8 in the evening of Sept. 5, 1837. At the edge of the placenta there was a thickened flap of

skin about an inch and a half long, and three-quarters of an inch broad, which was connected with the membranes of the ovum; there were no blood-vessels to be seen in this appendage, nor did it seem to be of a fatty nature. As Dr. Siebold did not know what to make of it, and this irregularity of the membranes of the ovum did not seem worth preserving, the afterbirth was put aside. The afterpains continued until 10 o'clock in the morning of the third day, when something protruded from the genitals, having the appearance of a longish oval flap of the skin, of a pale colour, but with no perceptible smell of putrefaction; it was $3\frac{1}{4}$ inches long, and $1\frac{1}{4}$ broad. On more accurate examination Dr. Siebold found that it was a fœtus of about four months, squeezed quite flat. Its head was pressed together laterally, with the face turned to the left. The remains of the eyeballs gleamed with a blueish hue through the closed eyelids. The neck and trunk were flattened from before backwards; the ribs and their cartilages were easily distinguished, and not one of the former was broken. The right arm was bent obliquely over the chest, and pressed close to it. The right hand was perfectly formed. The left humerus was extended upwards behind the left side of the face, but the fore arm was lost. The right leg was turned upwards, so that feet and toes could be pretty clearly distinguished; but of the left lower extremity only the femur was left, with the muscles surrounding it. The external male genitals were also distinguishable. On the abdomen there was a remnant of the funis in the form of a flat and narrow ligament three inches and a half long, with the maternal extremity unattached and lacerated. The whole back of the body was as it were corroded, so that in many places the bones of the fœtus were laid bare.

It was beyond all doubt that this fœtus was the twin brother of the child which had been born alive, and that both germs had been impregnated at the same time. One of the embryos died in the fourth month of its formation, and was gradually compressed against the internal surface of the uterus. The peculiar flap on the membranes of the child born at its full time may possibly have been the relics of the membranes belonging to the ovum of the fœtus which perished. Dr. Siebold is very sorry that he did not make a preparation of it. He doubts this being a case of superfœtation, indeed he doubts the possibility of its occurrence; and is inclined to believe that in most of those instances which are supposed to prove a superfœtation, either there were twins, and one fœtus came into the world too soon, or too late; or else the case has been narrated so imperfectly as to prove nothing on either

side of the question. So far Dr. Siebold. Dr. Meissner, who reports the case in *Schmidt's Jahrbücher*, observes that even when both children are born alive and of apparently different ages, it is not a proof of superfœtation. He once saw a case where of two children born at the same time one was at the full period, and the other, though born alive, was apparently a seven months child, and weighed only two pounds and a half; yet both had a common placenta and a common chorion, but the amnion was double. This case proves that from some circumstance a twin child may be retarded in its growth. Immediately after this case we find one of the same class where triplets were borne. On the 1st April 1838, says G. A. Michaelis, M. P. was prematurely delivered of two boys, both dead; on the 16th of July she was delivered of the third child of the triplet, who was alive and well when the case was reported in *Pfaff's Mittheil*, 1838, Hft. 9 and 10.

SPONTANEOUS DISCHARGE OF A CALCULUS,

OCCURRING TWICE IN THE SAME PATIENT.

At the meeting of the Wurtemberg Medical Association, held at Tübingen, May 14th, 1838, Dr. Koller, of Hechingen, related the following interesting case.

A boy aged $4\frac{1}{2}$, the son of poor country people in the village of Füngingen, had long suffered from scrofula and rickets, and during this period often scratched the lime from the walls, and swallowed it with greediness, but had never had medical advice. In the spring of 1828 he first laboured under slight urinary disorder, which from time to time disappeared and returned. Dr. Koller was called in, and after a gentle laxative, ordered hemp-seed milk to be taken as a drink, a prescription which was followed for a long time. But by the beginning of July, the symptoms had become so severe, that Dr. Koller was again consulted; and on examining with the catheter he found a stone, and proposed to the parents to operate. They would not consent, however, though fever began to set in, and though the child complained of the increased severity of the pain, while the scrotum swelled, inflamed, and ultimately mortified, so that small openings formed in several places, through which urine and matter trickled forth. As it was now necessary to give up the operation Dr. Koller prescribed the mineral acids and bark internally, and tonic and aromatic poultices externally. On the following day, on which several sloughs had been already thrown off, exactly at the time of Dr. Koller's visit, the patient felt a violent inclination to evacuate the

bowels and bladder, and on sitting upon the chamber-pot squeezed out a calculus weighing 129 grains. The urine now flowed without obstruction through the passage by which the stone had been discharged. The previous remedies being continued, all the sloughs were soon thrown off, and within a fortnight the destroyed parts were regenerated, so that only a few drops of urine trickled from the wound, while a full stream was discharged from the urethra. In three weeks the child was quite well, had a more healthy appearance, and continued to grow. From this period, Dr. Koller only saw the patient occasionally and rarely. Meantime the boy had attained the age of 15, and had gone to service, when in Feb. 1838, after an interval of ten years, he was attacked with difficulty in making water, and pain, so that he was obliged to leave his situation. This time Dr. Koller was not called in, but a barber of the place. The case went on, as on the former occasion. The scrotum inflamed and mortified, and in a few weeks a calculus weighing 90 grains was discharged just like the former one, except that its passage was facilitated by an incision into the mortified part of the skin of the scrotum. The wound healed like the previous one, and with the same rapidity. — *Wurtemberg. Correspond. Bl.* and *Schmidt's Jahrbücher*.

APPLICATION OF IODINE EXTERNALLY.

To the Editor of the Medical Gazette.

SIR,

In last week's GAZETTE a correspondent, who signs himself ΘΕΡΑΠΕΙΑ, directs the attention of its readers to the use of iodine as an external application in chilblains, informing them at the same time that he is not aware that the remedy had ever before been either employed or recommended for that complaint. In the latter respect your correspondent is in error in supposing that he is the first to suggest such an application for chilblains. If ΘΕΡΑΠΕΙΑ will do me the honour of referring to a little work published by me about nine months ago, entitled "Selections in Pathology and Surgery," he will there find that I have been in the habit, for more than ten years, of using iodine externally, both in the form of tincture and of ioduretted hydriodate solution; and he will perceive, by turning to page 119, that chilblains is one of the diseases especially chosen with the view of illustrating the employment of the remedy.—I am sir,

Your obedient servant,

JOHN DAVIES,

Surgeon to the General Infirmary.

Hertford, March, 23, 1840.

THE CLIMATE OF CUBA.

ALTHOUGH the mountains of Cuba are not so high as those of Jamaica, or St. Domingo, the more northerly situation of the *Grande Antilla* gives a greater range to the thermometer than in any other of the West India islands. It has never been known to snow there; but frost occurs occasionally; and ice has been formed when a strong north wind has for some time prevailed, bringing with it the cold air of the Canadas. This took place in 1801, and again in 1812, on some high ground in the neighbourhood of the Havana, above 350 feet above the level of the sea. Hail storms are not so uncommon, occurring in general when the wind is blowing strongly from the S.S.W.; and on the tops of the highest mountains, after a copious dew, the ground is frequently whitened with hoar frost.

Instead of summer and winter, the seasons are spoken of as the rainy and the dry, although the period of demarcation is not very clearly defined. It is generally in May that the rainy season commences; but sometimes it begins in April, and occasionally not till June. Of late years, however, the island suffers much more from excessive drought than from rain. In some districts a fourth or a third part of the cattle have been cut off; and, at other places, as much as a half, from the mere want of water. The crops have probably suffered in an equal degree, though the amount of the loss is not so easily determined. These droughts are ascribed with every appearance of truth to the cutting down of the timber; and it has even been recommended that the local authorities should interfere to restrain the proprietors from denuding their estates, especially on the mountainous ridges of the great Cordillera, so as to save some portion of the native forests in the most favourable situation for attracting the moisture. The history of some of the longest settled islands in these seas seems to justify this suggestion, as we find that Antigua and Barbadoes, which now so frequently suffer from a season of drought, had nothing of that kind to complain of, in the first century of their settlement, before the trees had disappeared. Hurricanes are not so frequent in Cuba as in St. Domingo or the Leeward Islands, as, by a strange perversion of language, the smaller islands of the Archipelago are denominated in our Post-office department. When they do occur, it is generally between the middle of August and the middle of October. The French government assume that the dangerous season is from the 15th of July to the 15th of October; and, during that period, they compel their

merchant ships, in the West Indies, to retire from the open roadsteads to places of greater safety. Spanish vessels are not exposed to any restraint beyond the practice of the underwriters in the marine insurance, who are accustomed to increase their rates of premium on ships going out to sea after the 1st of August.—*Cuba: with notices of Porto Rico and the Slave Trade. By David Turnbull.*

[In another place Mr. Turnbull says, "Even here, in the empty boiling house, I found a poor negro with one leg in the stocks. The night before had been piercingly cold, as it often is in Cuba; and negroes are proverbially more sensible to it than white men. I need not say, therefore, how horrifying was the unheeded appeal of the solitary prisoner to the mayoral as we passed, of "mucho frio! mucho frio!" (We may mention, in passing, that Mr. Turnbull's account of slavery and the slave trade is very instructive.) Dr. Chervin, in the letter which we gave at p. 636 of our last volume, speaks of a temperature of 59° of Fahr. at the Havana, as if it were very low; but he speaks of the plains, and a great part at least of Mr. Turnbull's account appears to be limited to the hilly districts.]

LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

ARTERIAL SYSTEM—*continued.*

WOUNDS — *Varieties — Diagnosis — Treatment, by Astringents and Styptics, Absorbents, Cauterisation, Suture, Acupuncture, Electropuncture, Seton, Compression, Machure, Refoulement, Torsion, Ligature.*—ARTERITIS.

THE puncture of an artery may occasion, at first, a considerable hæmorrhage, but it is usually soon moderated; blood escapes into the sheath, parallelism is destroyed, a coagulum is formed, the opening is blocked up, and the artery remains permeable: occasionally, however, the hæmorrhage is very obstinate, and it was in consequence of this circumstance that the ancients recommended and we employ complete section. Simple punctures have occasionally given rise to secondary hæmorrhage; Guthrie relates two cases in which the femoral artery was wounded with a tenaculum, and in which consecutive ulceration took place, followed by hæmorrhage. When there is a longitudinal or oblique wound, (Fig. 1 and 2) the blood escapes in greater abundance than where there is simple puncture, but is arrested in a similar manner. Sometimes the vessel remains permeable, sometimes it is obliterated.

A transverse wound, not implicating more than a fourth of the circumference of the vessel (Fig. 3), takes a rounded form. As in the former case, blood coagulates in the sheath, lymph is secreted, the opening is blocked up. The cicatrix in these three cases is permanent in horses and dogs; not always so in man. In him, immediate

union of the lips of the wound very rarely occurs; there is always a new substance interposed. This substance not uncommonly gives way, and a consecutive aneurism is the consequence. If the wound affect one-half of the circumference of the vessel, the lips of the wound are still farther separated: blood flows freely, and longer than in any other species of arterial wound. It may continue until death, which is then rapidly brought about; it may be suspended by syncope, may re-appear with returning strength: then death does not occur so speedily. In those cases where death has not been the consequence, which, if the artery be large, is very rare, syncope being prolonged, a coagulum is formed, and the vessel may be obliterated. If *three-fourths* have suffered (Fig. 4.), the retraction is so

FIGS. 3, 2, 1, 4.

considerable that the edges of the vessel seem as if hollowed or bevelled out, and the diameter of the vessel is lessened. Here the cure is much more probable than in the preceding case.

Arteries may be wounded by *excessive distension*. The internal tunic first gives way, then the middle—beyond this, such an injury cannot extend. This accident may give rise to aneurism or obliteration. In certain luxations, it is

said, all the tunics may give way. These injuries are not followed by hæmorrhage, or, if blood escape at all, it is soon spontaneously arrested. A *contusing body* may partially or totally destroy the arterial tunics. On the field of battle both are common; but hæmorrhage from such accidents is unfrequent. Berard describes such a case; in which, with a scissors, the jagged end was removed, and hæmorrhage immediately followed. However, in those cases, it is usually secondary hæmorrhage, upon the throwing off the eschar, from which we have most to apprehend. The hæmorrhage following wounds of arteries may destroy life in a few moments; or it may be renewed at intervals, and death may be less speedy.

The condition of the blood exercises a certain influence upon hæmorrhage. When it flows abundantly, and only once, from a wound made in a vigorous man, the latter portion coagulates at the moment between the lips of the wound. If, instead of that, hæmorrhage is re-produced several times at certain intervals, the blood becomes serous, and the chance of spontaneous suspension is less.

With reference to the maintenance of the circulation, wounds may be divided into two classes; the one totally intercepting the passage of the blood beyond the point, the other permitting it. The first class, affecting the principal artery of a limb, may occasion gangrene; and this is more especially to be apprehended, when the satellite vein has been at the same time implicated. Guthrie speaks of it as following a wound implicating the femoral vein and artery, gangrene commencing in the toes. The ancients believed, in such a case, gangrene to be inevitable; but there are many exceptions to this rule.

Diagnosis.—A wound being made, and the quantity of blood shed being disproportioned to its extent, we believe a blood-vessel has been implicated. We first seek to determine whether it be an artery or vein. The situation of the wound, the jet, and the colour of the blood, do much in enabling us to ascertain this point: but artery and vein may be wounded, the blood is mixed, its appearance is modified. We may now employ another means of diagnosis, compression. If we press between the heart and the wound, only dark blood can flow; if between the wound and the capillaries, arterial blood alone can flow. But difficulties will still present themselves. The jerk is wanting when the wound is deep and irregular; besides, a jet of vermilion blood may be seen when only a vein is wounded; it may be dark when arterial. In some individuals suffering from fever, the circulation is naturally rapid, being accelerated by the disease; if we bleed them, the blood is shed in jerks,

and, towards the end of the bleeding, becomes so red, that it might readily be supposed that the artery was wounded. As to the second point, Hunter observed, that the blood might escape dark from the superior extremity of the artery when pressure is made above the point, and in certain diseases in which arterialisation is incomplete.

It is also desirable to ascertain whether the trunk or a branch be wounded. Again, when consecutive, it is of importance to ascertain whether it escape from the superior or inferior portion of the artery. This can only be done by compression above and below the wound, and by narrowly observing the effect.

Treatment.—The means which are employed for restraining hæmorrhage may be temporary or permanent. For instance, blood flowing in large quantity may destroy life rapidly, therefore it is necessary to act at once; and this will appear more imperative if we admit, with Morand, that of those who die on a field of battle three-fourths are from hæmorrhage. Now, nothing is easier in a large number of cases than temporarily to command a hæmorrhage. In an operation it often becomes a question, whether we should tie a bleeding vessel at the time, or continue the operation. Guthrie states, that the slightest pressure made by the finger and thumb upon a bleeding artery will suspend the hæmorrhage; pressure upon a limb would have the same effect. It often happens, that the means which we employ as temporary agents definitively arrest the hæmorrhage; this is particularly seen in the removal of a cancerous breast. If the vessels can be seen, they should be treated as if they poured out blood. The fundamental indication is, of course, to obliterate the wounded vessel; for we cannot rely on the lateral cicatrix, even if the case would admit of its being obtained. When small arteries have been wounded, either by accident or during surgical operation, the immediate object is to bring together the lips of the wound. Now the pressure so made will often arrest the hæmorrhage, and render it unnecessary to interpose any foreign body; the operation for hare-lip is evidence of that fact. The early operators by the flap method in amputation, insisted strongly on this as one of the great advantages of that operation. When blood oozes from all parts of a surface, and when, after sponging it, we cannot discover any orifice, we may apply cold astringents or styptics; we may plug with lint, amadou, or agarie. The concurrence of a spongy substance and moderate compression is in most cases preferable to astringent powders or styptics. If, in a wound recently made, we can distinguish the ends of a wounded artery, it

is necessary to apply upon each the agent we employ, as the anastomosis may equally cause hæmorrhage from the inferior extremity.

Experience has shewn, that inflammation and obliteration of arteries may be occasioned by introducing into their cavity styptics of various kinds, solid as well as fluid; mechanical obstacles, such as bougies, doe-skin, and other similar means. yet they cannot enter into comparison with the ligature, or even torsion. If the wound be very deep, and affect by contiguity important organs, a question to consider is, whether we shall enlarge the wound, and seek for the artery, or tie it at a distance. We may tie at a distance, and prevent farther loss of blood from the side next the heart, but blood will continue to flow from the farther extremity; and if, as maintained by Mr. Guthrie, the inferior end is more exposed to hæmorrhage than the superior, the evil is not controlled. Mr. Guthrie, therefore, maintains the necessity of cutting down upon the end in most cases; but, unquestionably, there are cases where this practice is unwise. Where the parts around are much disturbed, infiltration, fracture, and other circumstances, render it necessary to tie at a distance; but no definite rule can be laid down for such special cases. There are certain arteries which, from their situation, cannot be so treated: those of the perineum, for instance. We may get hold of them with the forceps, but that is only half the business. To obviate the difficulty, forceps have been invented which may be permanently applied: others employ torsion; others, "froissement." Certain arteries may be commanded by pressure; the temporal, auricular, occipital: but, even here, I prefer the ligature. There are arteries which can neither be tied, twisted, nor compressed—the nutritive artery of the tibia, the meningeal, the epigastric, wounded in paracentesis: others, which have undergone calcareous transformation. In these cases plugging has been tried; indeed, in certain cases, cauterisation must be employed. In the present day we are not justified in recommending amputation to cure hæmorrhage; but if the artery and vein be wounded, and gangrene be imminent, it must be done.

In restraining hæmorrhage or obliterating arteries, we may employ a great variety of agents; such as, 1st, styptics, refrigerants, cauterisation, plugging, suture, seton, acupuncture, electro-puncture. Second, compression, plugs, "marchure," réfolement, torsion, ligature.

Among the *astringents* and *styptics* employed to restrain hæmorrhage, or to obliterate arteries in their continuity, are, cold air, cold water, ice, acidulated water,

preparations of copper and iron; but they are applicable only to cases where a small artery is opened, or to an aneurismal tumor. Many surgeons are partial to the application of ice, but unquestionably, except in special cases, it has little value; long continued, it exposes to gangrene; but there are cases where it may be found useful.

Among the *absorbents*, many of which are also astringents, are lint, sponge, certain powders, agaric, &c. Again, we may say, these can only be employed with good effect when the hæmorrhage is inconsiderable.

Cauterisation has been used to restrain bleeding even from large arteries. The ancients employed boiling oil and the red-hot iron; for the same purpose, they amputated with red-hot knives. Besides the cruelty of these means, they cannot be depended on; they often restrain the hæmorrhage only so long as the eschar which they produce remains attached. In the present day, few of these substances are employed. The actual cautery is sometimes used after the excision of hæmorrhoidal tumors, after the removal of deep-seated tumors in the zygomatic fossa, after the ablation of the maxillary bones and tumors of the gums; but then it is employed for two purposes—that of staunching the blood, and destroying any diseased structure which may remain.

Guattani, in a case of aneurism of the external iliac, cut down upon and opened the tumor, extracted the clot, filled the sac with agaric, maintained it there by means of compresses and bandages; but this is clearly not an example to be followed.

Lambert advised that the lips of a wounded artery should be brought together and united by *suture*, under an idea that its permeability would be preserved. This is not the only method which was suggested under the apprehension that the collateral circulation was insufficient. But since it has been established that an aneurismal tumor cannot be cured, at least with any certainty, without obliteration of the diseased vessel, and the resources of the anastomosing system are better known, this means has been abandoned.

Acupuncture has been applied to the obliteration of arteries. Velpeau and myself, at the same time (1830), made experiments on this subject. The result of his experiments made upon dogs, was, that an artery of the size of an ordinary writing pen may be obliterated by a single pin, and that for larger arteries more pins are required, to produce this effect. Amussat's experiments tend to prove the insufficiency of pins to excite the necessary inflammation for the obliteration of large

arteries. My objections were, that we had no security that the pins had transfixed the artery, and that even when they had, they occasionally failed in procuring its obliteration.

Electro-puncture, which I also applied in 1830-1, fails from a similar cause—uncertainty whether the artery is transfixed; but applied to the sac itself, the result is different.

The *seton*, applied to the continuity of arteries, is equally uncertain; in fact, we can have no security that the agent is applied, unless we cut down upon and expose the artery; and if that be done, we had better apply the ligature: besides, neither acupuncture, electro-puncture, nor the seton, are available in cases of hæmorrhage.

Compression has in all times been extensively employed, both as a temporary and a permanent means of restraining hæmorrhage. It may be applied directly upon the bleeding point; but then it is, or should be, a temporary agent, for which another should be substituted. Compression is commonly applied at some distance from the injured point; for instance, preparatory to amputation or removal of a tumor. For the purpose of suspending hæmorrhage during operation, the ancients would seem to have employed compression, but in what manner they applied it, is not clearly shewn. Paré is the first person from whose writings we derive any accurate idea of the mode in which compression was employed; but his circular pressure was an evil agent. This arrangement was improved upon by the interposition of a pad over the course of an artery. In 1674, Morel invented the "garrot;" which was afterwards variously modified, and by which any extent of pressure might be made by twisting the piece of wood attached to it. In 1718, Petit presented to the Academy of Sciences a tourniquet which he had invented, for the purpose of commanding hæmorrhage in amputation of the thigh: since his time, the tourniquet has been variously modified, but the principle still remains unchanged. If assistants are few, this instrument is of first-rate importance; but it cannot be compared with the hand of a steady assistant, furnished, or not, with a padded key. All places are not equally proper for making compression; the artery should be superficial, and supported by a bone; but, then, few arteries present these two conditions, except the brachial, the radial in its lower third, the femoral upon the pubis: still we may compress, though with less certainty, the axilla behind the clavicle, upon the first rib, the femoral near the middle of the thigh. Other arteries are, it is true, placed superficially,

but rest upon parts too soft and flexible to admit of compression. Others are placed over proper supports, but then they are too deep seated to be readily acted upon. Such is the compression of the abdominal aorta upon the spine. It is sometimes employed to obliterate small arteries resting upon bones—those of the head, for instance. Generally, however, direct pressure is an uncertain means—is inconvenient, from its irritating the surface of a wound and opposing union by first intention. In many regions it is utterly impracticable, for want of the necessary elements of success. When we employ circular compression upon a limb, to prevent congestion at its lower part, it is necessary to bandage from below, until we cover the compresses which may be placed on the wound. When our object is to obliterate the artery, the compression must be long continued: if it be removed before the clot is adherent, hæmorrhage will infallibly occur. Again, we apply it to repress hæmorrhage from mucous surfaces, by plugging. This is employed in hæmorrhage from the nose, the vagina, the rectum. The plugging material may be impregnated with sulphate of copper, or other styptic or astringent substances. Usually, plugging should not be had recourse to till other means have failed: it always irritates the parts with which it is in contact; if the parietes be muscular, like the rectum, it excites contraction.

We may now indicate points at which compression may be applied. The *common carotid* rests upon an osseous plane formed by the cervical region of the spine; at its superior part, it is easily felt under the skin. We may there compress it with the fingers, but the vicinity of the larynx renders the operation difficult and fatiguing. The *external maxillary* is very easy to compress at the moment it passes under the ramus of the jaw, in front of the masseter muscle. The *temporal artery* may be compressed in front of the ear, two lines from the base of the tragus. The *subclavian* it is difficult to compress; the omoclavicular space is singularly variable; according to the curvature of the clavicle, the artery is found at different depths; the thumb, supposing it may get to the necessary depth, will soon be fatigued, but whatever mode of compression may be used, it is uncertain. The *axillary artery*, Dahl believed, might be compressed below the clavicle, taking as a support the second and third ribs. With the fingers it is impossible efficaciously to compress through the thick muscular layer between them and the vessel. In the axilla it is different; the head of the humerus serves as a point of support: compression, whether by the fingers or otherwise, must be ap-

plied upon the point which separates the anterior from the middle-third of the axilla. The *brachial* artery may be compressed along the whole arm, passing, as it does, along the internal border of the biceps; the large nerves which accompany it, assist in finding it, but they render compression painful. The *radial* artery may be compressed where the pulse is felt. The *ulnar*, outside of the tendon of the flexor carpi ulnaris. The *abdominal aorta* may be compressed upon the lumbar vertebrae: the four fingers should be ranged upon the linea alba; the patient should be so placed as to relax completely the abdominal muscles. In the *external iliac*, after relaxing the abdominal muscles, pressure should be made at the edge of the superior outlet of the pelvis, compression being applied a little outwards from that point. In the *femoral*, compression is most important, most sure, and most employed. The ileo-pectineal eminence is the point of support; the thumb answers very well; it should be placed across the vessel. At the middle-third of the thigh, the femur itself serves as a point of support. There a tourniquet answers well. In the ham it is much more difficult to compress, because of the depth at which the artery is situated; the fingers would be too soon fatigued, and the tourniquet would be too painful. The divisions of the femoral may be compressed at different points where we tie them, but such compression is rarely used.

A very early idea entertained on the subject of restraining hæmorrhage, was, that excentric compression might avail; this was to be effected by introducing certain substances within the arterial tube, like a cork in a bottle. In the works of Avicenna it is held to be very important. Many surgeons have employed it where an artery was so much ossified that it was likely to give way under the ligature, as usually applied. A bougie may then be introduced, and a ligature placed around the vessel, so as to keep it there. Before, and indeed after, Paré's time, cones of alum or sulphate of copper were introduced; these cones did not act by compression, but by exciting arteritis.

Machure, or gnawing, is a term employed in consequence of the fancied similarity of the operation to that performed by brute animals upon the umbilical cord. In 1820, Maunoir invented pincers with which the internal coats were injured to the necessary extent, but it is an uncertain method of treatment. Usually it will be found that where the artery is thus pinched, there will be a tendency to form a coagulum; but to render coagulation more probable, it should be made to act on several points.

Refulement, or inversion, is performed by seizing an artery by means of a blunt scissors or forceps, so that the internal and middle tunics shall be ruptured. When this is accomplished, the instrument is not removed, but it is pushed towards the heart, and it will carry with it those tunics. I merely indicate these means for the purpose of shewing the agents which have been employed.

The *torsion* has been very frequently used; but though the modern French seem to dispute the priority of the invention, there can be no doubt that it is indicated by *Ætius*—that it was pretty distinctly described by *Peyrilhé*, or, indeed, that *Léveillé*, in 1812, textually cited the passage from *Galen*. In performing this operation, which may be employed on the continuity or upon the cut extremity of an artery, it is well to be provided with forceps of a particular construction. Upon an amputated surface, an artery is seized with a common forceps; it is drawn forward, and, with another forceps, is separated as completely as possible from adjoining parts. The vessel being drawn forward to the extent of five or six lines, with a torsion forceps held in the right hand, the artery is seized perpendicularly to its axis, and the forceps is then fixed. With a second forceps the vessel is then grasped at the level of the wound, and the internal and middle tunics are ruptured. The fixed forceps is now twisted round, until the vessel has revolved seven or eight times on its own axis: beyond that, the twisting process must not be carried, or the end of the artery may come off. In applying this method to arteries in their continuity, *Thierry* passes *Deschamps*'s needle under the artery, which he twists, and proportions the revolutions to the size of the artery.

The operation of the *ligature* of arteries is so important to the surgeon, that it is essential it should be well considered and well understood. I believe the ligature was employed at a very early period; but the first formal mention of it is contained in *Celsus*. Even in his time the application of it was very limited; for he insists upon hæmorrhage as one of the most formidable of the dangers attendant upon amputation, and recommends, for restraining it, plugging, venegar, &c. Indeed it is not clear that the ligature was employed to restrain hæmorrhage after amputation before the time of *Paré*. The employment of the ligature by means of the forceps seems not to have been adopted till after the time of *Petit*. *Paré* employed it by including the artery and surrounding structures by means of a needle. *Petit* preferred pressure, and cauterly unquestionably. Indeed, the Academy of Surgery

for some time preferred styptics and agaric to the ligature. Heister recommended that the ligature should be used with the forceps; but, perhaps, Monro most powerfully contributed to induce surgeons in the last century to adopt the ligature upon the artery without including adjoining structures: he also proved that the pain of the ligature, at the time of application, is not great; that it does not subject the patient to violent consecutive pain, convulsions, inflammation, or suppuration, and that it is detached with facility.

Before we proceed further we must consider the different methods of applying the ligature, and the effect which a circular constriction produces. Jones, Vacca, Beclard, Travers, Mance, and others, have carefully investigated this subject, and ascertained that the first effect of a ligature, tightly drawn, was to make a fair and complete circular incision of the internal and middle tunics, and a puckering of the external coat of the artery. Soon a coagulum is formed, which extends from the ligature towards the first moderate collateral branch, which is given off by the vessel: this clot is as much larger and longer as the collateral vessel is further removed from the ligature. It completely fails if between the two points there be no more than a space of two lines, and if the arteries be voluminous. In the succeeding twenty-four hours coagulable lymph is secreted and deposited between the clot and the internal tunic, and causes intimate union between these parts; an analogous secretion occurs external to the vessel, so that the two extremities of the artery are plunged in the midst of an organisable mass, which assures the future obliteration of the vessel. The secretion of this matter within the vessel is certainly more abundant when the internal and middle tunics are fairly cut through than when they are merely brought together. This lymph becomes more and more solid, passing through the different stages of organization. During this time the thread excites, at the point where it is applied, ulcerative inflammation, and, in process of time, the artery is fairly cut through. If the process be interrupted—if the irritation be too great, purulent matter may be poured out either externally and internally, or both. Most commonly the secretion of pus is trifling, and confined to the point where the ligature is found, ceasing when that is removed. In either case the course of the blood is interrupted; first, by the fibrinous clot which partially fills the vessel; second, by the lymph which retains the clot in its place, and maintains the puckering which the ligature produced; third, by similar lymph effused externally, which supports the extremities of the

artery as the two ends of a fractured bone are supported by callus. Gradually the clot is absorbed, the parietes approach, unite from the ligature to the collateral, and the artery is entirely obliterated to that extent, and is ultimately transformed into a fibrous cord, which eventually disappears.

If the process we have described be interrupted by violent or specific inflammation, the obliteration of the vessel is only temporary; and when the ligature comes away, the non-adherent clot is forced out, and blood flows. Hæmorrhage should be apprehended if the ligatures have been applied too near the origin of a moderate sized branch; the formation of a clot, in that case, being impossible or imperfect. Still, in this case, nature may prevent the effusion of blood; lymph may fill up the part between the ligature and the collateral, and at the same time surround it externally. Under whatever circumstances the ligature be employed, the main phenomena are the same. The time necessary for the obliteration above and below the ligature, so as to resist the impulse of the blood, is variable; usually as much shorter as an artery is smaller, as the ligature has been placed farther from the point where a moderate sized collateral is given off, as the artery is healthy, and as the general health is good. The ligature has been detached from the femoral in six days without hæmorrhage, and in eighteen with. Usually it happens from the eleventh to the twentieth day; but from the fourth or fifth the superior extremity is no longer permeable.

Many persons have conceived that a simple division of the internal and middle tunic by a ligature, which is removed in a few minutes, was sufficient to effect obliteration; and this induced the trial of *temporary ligatures*, which present one material advantage—that of allowing union of the wound by first intention; but unfortunately the experiments of Travers, Dalrymple, and Hodgson, do not justify the hopes which were entertained of them. Sometimes, when the ligature has remained in place twenty-four hours, obliteration has occurred; but there is no certainty; and the presence of the ligature for twenty-four hours would be enough to prevent union by first intention. Scarpa, however, who clung to the idea that the ligature should be removed at the earliest possible moment, found that it might be removed in from three to five days.

But although, in ordinary cases, adhesive inflammation sets in rapidly, it is not always so in feeble subjects—those in whom the artery is either diseased or fragile: in these cases the ligature may cut through the coats without interrupting the current of blood, and hæmorrhage the

most grave may follow. To prevent or repress such hæmorrhage, the ligature "*d'attente*" was introduced, and applied in the following manner:—above the constricting ligature one or more others are applied, to be constricted if the one fail. Hunter and Desault had another object in view; they successively constricted them, increasing from the superior to the inferior, for the purpose of gradually diminishing the power of the current before it arrived at the constricted point. The use of this plan is exploded. In the present day we are fully sensible of all the mischief of denuding the artery and interposing so many foreign bodies, producing suppuration and other inconvenience; besides, if the first ligature failed, it is almost certain the second would do so likewise, as the inflamed artery would be at once cut through by the tightened ligature.

Again, it was the custom of the ancients to apply two ligatures upon a vessel, and make a section between them. After having been long abandoned, it was resuscitated by Bell and Abernethy, and by M. Maunoir, who published, in 1802, a pamphlet on the subject. They maintained that arteries are strongly retractile; and, when puckered by means of two ligatures, they are violently dragged at each impulsion of the heart; and that to prevent this it is prudent to place the arteries in the same condition as after amputation. So much is certain: hæmorrhage after amputation is less frequent than when an artery is tied in its continuity. This is denied by some persons; but it is no less a fact. The views of the persons who resuscitated this plan have not been sanctioned by experience: often after the employment of this method hæmorrhage occurred: besides, it is not applicable to those regions where the artery can only be exposed to a very small extent.

Scarpa, who had serious apprehensions of the danger attendant upon the section of arterial tunics, sought to bring them into apposition without accomplishing the division; for this purpose he used flat ligatures, and interposed between them and the artery small rolls of lint or plaister, drawing the ligatures moderately tight. This ligature was removed at the end of three or four days, a time sufficiently long, in his opinion, to secure adhesion; but, at this time, it is not always easy to remove the apparatus; and Scarpa found it necessary to invent an instrument to accomplish this object. The idea of the roll, however, belongs to times anterior to those of Scarpa—those of Dionis, Pàré, Platner, Heister; but the application of the principle belongs to Scarpa. In the present day, the use of the ligature and cylinder is almost totally

abandoned, except where the artery is so fragile as to excite well-founded apprehension that it would not resist the ordinary ligature. We have also abandoned the various forceps by means of which the same end was sought to be obtained; they irritate the wound; they dispose the artery to ulcerate, and only incompletely obliterate the vessel in many cases.

Various ligatures have been employed to tie arteries: for many years men sought to discover some agent which might be absorbed, or remain at the part without exciting irritation, and so constitute no obstacle to immediate union; and many substances were used—doe-skin, cat gut, silk, metallic substances, but most of them were soon abandoned, and ligature silk is commonly preferred.

Again, the form of the ligature has been much dwelt on; one party, wedded to the section, preferring round and small; the other, dreading section, and only requiring apposition, chose to employ flat ligatures. Observation, on a large scale, has demonstrated that large flat ligatures, applied on healthy arteries, give no more protection than the most delicate, and are much more inconvenient.

Some men have recommended that the ligature should be cut off close to the knot. Its sojourn under the skin is not usually very inconvenient; commonly they occasion little abscesses, and are discharged with the pus contained in them. Lawrence, Travers, Delpech, and Beclard, have recommended that plan.

Our next point is to consider the modes of applying the ligature, and, first, we will examine it upon an amputated surface. Your anatomical knowledge will inform you where the artery should be found; you pass a tenaculum through it, or seize it with a forceps; it is drawn forward as little encumbered as possible with surrounding tissues, and the ligature is applied. In tying the artery, its cellular sheath should be included; if this be not included, the section may be completed before the vessel is obliterated. The constriction ought to be sufficient to cause a bulging above and below the ligature; and we may then be satisfied that the internal and middle tunics are incised, the external only remaining entire. When the surface does not bleed, although we know that vessels open upon it, all compression on the course of the vessel should cease; the surface should be sponged with warm water; the spasm may then cease, the course of the blood be re-established, the arteries jerk, and the ligature be applied. If we have to apply a ligature in the course of the vessel, which we may have to do for aneurism, hæmorrhage, and for the purpose of repressing the growth

of certain tumors, we place the limb upon which we have to operate in a semi-flexed state; we direct the eye upon the course of the artery, we then explore with the finger, the only way of avoiding difficulties; we have preparations for compression, the finger or a tourniquet, to be used if necessary. I say if necessary, because I know nothing so desirable to avoid in the performance of an operation as the congestion which circular compression occasions. The artery having been felt, and the integument being tense, an incision from two to four inches long, parallel to it, should be made. The centre of the incision should correspond to the point in which the artery is to be taken up. It is better that the incision should be too long than too short: if the artery be deep, some prefer making the incision a little oblique. If the artery be superficial, the first incision should not be too deep; it is better to incise the skin at twice than to come down at once upon the sheath of the vessel. With much precaution the several fasciæ or muscular fibres should be cut, and the sheath opened with great care, and the artery disturbed as little as possible, to avoid supuration. The artery is easily distinguished by its dull yellow colour, by its flattening when pressure is made at a point nearer to the heart, by its beating when we press below. We must carefully separate it from veins and nerves. Whenever an artery is accompanied by a large vein, the needle should always be made to enter on the side of the vein, as there is less chance of injury. When the ligature is placed around the vessel, before it is tightened we draw it up for the purpose of ascertaining that the artery is really included; this is not always so easy a matter as may be supposed. Experienced surgeons have tied the median and other nerves for the artery. The operation completed, one end of the ligature is cut off close to the knot; the other brought out at the most depending part of the incision; the wound should then be brought together for the purpose of endeavouring to bring about immediate union, for supuration is always uncomfortable, as giving reason to apprehend hæmorrhage. The ligature of nerves is a serious accident, paralysis or tetanus may be the consequence. The ligature of veins is little less serious: if, at the same moment, we intercept the circulation in the principal artery and vein of a limb, gangrene is almost inevitable: the ligature of a smaller vein, although it may not cause gangrene, may produce phlebitis. In the present day, it is rarely that we employ the ligature with the view of commanding hæmorrhage during certain operations; still it is more commonly done in our own than in other countries.

It can rarely be required. In the disarticulation of the thigh it might be advisable if the patient were very feeble; and it were of great importance to prevent arterial blood-shed: it is, then, questionable whether it be not best to employ a broad ligature, and merely bring the parietes in contact, and tie the artery upon the surface of the stump.

In the application of the ligature there are certain general rules to be observed, certain guides which facilitate the operation. For instance, in the ligature of the subclavian, the clavicle determines the course of the incision. Again, each artery has a muscle, which might be regarded as its satellite: the sartorius may be said to fill that office for the femoral; the mastoid for the carotid; the biceps for the humeral; the supinator longus for the radial; the masseter for the facial: they regulate the direction of the incision. Again, certain muscles may indicate where the artery is to be tied: in the absence of the tubercle on the first rib, the scalenus anticus would be a guide to the subclavian. Tendons, and even nerves, are also important: in the ligature of the humeral artery the median nerve is a guide. Again, in tying the subclavian, we have the clavicle, the trapezius, and the mastoid muscles circumscribe a space of great importance. They constitute three starting points for the incisions, of which we must choose one. As a general rule, the arteries to be tied are found in triangular spaces; and one line of the triangle generally directs the incision. Occasionally these lines fail, the muscles being obscured by fat. When they fail we can use imaginary lines.

Great desire has been manifested on the continent to substitute the torsion for the ligature, in great operations, wounded arteries, and in cases of aneurism, and it is, therefore, right shortly to consider this question, and to examine the objections made to the ligature. What are they? Nothing against its simplicity, nothing against the facility of applying it, nothing against the pain which it occasions, nothing against its consecutive accidents. Now what are the objections which may fairly be made against the *torsion*? It is neither simple nor easy: its difficulty, then, is a strong argument against it. Hospital surgeons of experience have tried it, and failed. I know the answer to that is, that the operation was ill performed; but if this be the case with eminent operators, what is to happen with practitioners in the country, whose opportunities of doing such operations are unfrequent? To perform *torsion*, it is necessary to denude the artery to the extent of half an inch; this must increase the chances of hæmorrhage. It is said that *torsion* facilitates union by first

intention. This is not true; the hard twisted extremity of the artery is as much a foreign body as the ligature cut short. Again, may not the artery untwist? such things have happened in experiments. In many cases, on the dead body, the pressure of a syringe has failed to overcome the resistance; but can we compare the action of a syringe to that of the heart? Can we compare the dead body with the living? I have no wish to deny that success has often attended the use of the torsion; the facts are well established; but what means which has been resorted to for arresting hæmorrhage does not number certain successful cases? No one can deny that very grave cases of hæmorrhage have ceased spontaneously. What is required in an hæmostatic agent is, that its physical action may be sufficiently energetic, and sufficiently sustained to give nature time to develop the definitive means of arresting the hæmorrhage; and, so far as I know, for the accomplishment of this result, we know, at present, no means which should supersede the ligature. It is the ligature which should be, and which is, employed whenever an important artery requires to be secured. Whatever be the means we employ to repress hæmorrhage, there are certain circumstances to be borne in mind—certain things to be associated with them: among these, position of the part is most important, absolute quiet, the most rigid regimen, and many other things too obvious to point out.

ARTERITIS.

Redness of the internal tunic alone, certainly cannot be relied on as evidence of inflammation of that tunic; and therefore the opinion of Frank, so long followed, cannot in the present day be accepted. This redness is always a uniform tint, and is not produced by any vascular injection; in fact, it is, as it were, a simple dying or colouring. Rigot and Trousseau, some years ago, sacrificed nineteen animals, and examined the vessels successively at the end of one, two, three, four, twenty-four hours, and so on. In those which were examined at the end of a few hours, the internal tunics were perfectly natural; beyond twenty-four hours, they presented the redness we are considering. In winter this redness is more rarely seen than in summer; it is as much more tardily developed as the body longer resists decomposition. This redness is not accompanied by any other modifications in the physical conditions of this membrane. When this colour is found in the arteries, it may also be found in the veins and in the cavities of the heart; being dependent in each upon imbibition. This redness is often found in patches or bands which

corresponded to masses of coagulum which had rested on those points. It is quite true that this redness is very commonly seen in arteries in the vicinity of an inflamed part, but I hold it to be even then no evidence of inflammation of these tunics, but of the existence of a greater quantity of coagulum in those vessels. It has been peremptorily asked why, when two bodies are placed under exactly similar circumstances, the one shall, at the end of a few hours, present this character, the other not? Simply, I apprehend, because they have died of different diseases—because the condition of the blood was not similar, and because one resisted decomposition for a longer time than the other.

In the absence of any physical change in either of the arterial tunics—in the absence of any accidental production within the arterial tube or in the substance of the parietes, I am disposed to maintain that redness of the internal tunic is no evidence of inflammation. It must not, however, be supposed that I maintain that inflammation of this tunic cannot happen; it is only necessary to cut off the circulation through an arterial tube to procure adhesion of this surface; and adhesion, I apprehend, never occurs without inflammatory action. Take also the ductus arteriosus and the umbilical arteries as illustrations of this point. But although this redness alone be no evidence of inflammation, it is different when it occurs in conjunction with other changes, whether of that tunic alone or with the others which enter into the composition of the arterial parietes. If to this uniform colouring of the internal tunic be added a punctiform or arborescent injection of the other tunics, together with a thickening of either, the presence of solid coagula, false membrane, or pus in the interior, we can no longer doubt the existence of inflammation in these parietes. If, on the external surface of an artery, evidence of increased vascular action be found—if the vasa vasorum be enlarged and gorged with blood—if the cellular tissue which unites the internal to the middle tunic be friable—if these membranes can be separated from each other without difficulty—if coagula be found at the point, and the internal tunic has lost its polish—and if held between one and the light, it presents a shrivelled character—if there be an increase of the thickness of these parietes, with loss of consistency or elasticity, so as to give way easily under the ligature; then we may fairly conclude that inflammation has affected those tunics. But there are other features still more conclusive of the existence of this disease: lymph may be effused either upon the internal or external

surface, or between the parietes of the vessel, and may become organized, as in serous membranes—may present the characters of a serous, fibrous, fibro-cartilaginous tissue—or may be transformed into calcareous laminæ; may arrange itself within the canal as a stratum concentric to the internal tunic, or as floating flakes, or it may constitute masses of sufficient bulk to block up the vessel. Hodgson has seen the subclavian obliterated in this way. Pus may be secreted and deposited within the vessel, but more frequently between the several tunics. Andral has seen the internal membrane of the aorta raised by half a dozen small abscesses filled with pus. These small abscesses between the internal and middle tunics, end by ulcerating, and their contents are evacuated. Those small ulcerations often seen on the internal surface of the aorta, are, no doubt, thus produced. They are sometimes as large as a fourpenny-piece, but usually superficial. Meckel describes a case which clearly establishes this point. All these phenomena are seldom observed together. Sometimes, with a change in the consistency of the parietes, we may find pus or lymph; at others, we shall find false membrane, with coagula. Sometimes, with false membrane, there is a coagulum separated from the arterial tunics by this membrane; more frequently, however, when a coagulum exists, it is in more or less direct contact with the internal tunic. I would therefore say, that inflammation of arteries, and indeed of veins, is manifested by a more or less marked redness of the internal tunic; its polish and glisten are lost, it appears dull and villous, and may be detached from the middle tunic with more or less facility. The vasa vasorum are injected and distended to some distance on either side of the inflamed point; but if the inflammation be considerable, they are lost in the redness and the tumefaction at the point. These vessels cannot be detected penetrating the internal tunic, but may sometimes be seen ramifying between that and the middle tunic. If the redness, joined to tumefaction, to softening, and to vascular injection, be good evidence of arterial inflammation, it is still more certain, if possible, when at the same time we detect other products of inflammation—lymph, pus, and false membrane.

A good deal of difference of opinion exists, as to what constitutes the first sign of inflammation of arteries. Sasse believed that the earliest sign of inflammation was a vascular injection of the external tunic. Gordon inclines to the same opinion. Cruveilhier states, that, in his experience, the first sign of a commencing inflammation is a coagulation of the blood circu-

lating in the vessel. To establish which of these opinions is the correct one, if either, would be extremely difficult, and could lead to no commensurate good. I have, however, no difficulty in stating, that Cruveilhier's opinion, that coagulation of the blood and obliteration of the vessel, are the inevitable consequences of inflammation of these tunics, appears to me too absolute. In some cases, the coagulum consequent on inflammation will not be of sufficient bulk to block up a large artery; it may constitute a cylindrical layer, through which the blood may pass. Although it may be laid down as a rule, that arterial inflammation almost necessarily brings about the formation of a coagulum of sufficient volume to obliterate the vessel, I am bound to state my belief that arteritis may exist, now and then, without obliterating an artery. It is not my purpose to enter further upon the subject of arteritis, than to facilitate the comprehension of the action of different agents upon these tubes, and the subject of aneurism.

ST. THOMAS'S HOSPITAL.

From the Report of the Commissioners for inquiring concerning Charities.

JOINT REPORT OF MR. WROTTESELEY AND MR. SMITH, DATED JUNE 1837.

This hospital was originally founded by Richard, Prior of Bermondsey, in 1213, for converts and poor children. It was remodelled in 1215 by Peter de Rupibus, Bishop of Winchester, whose foundation was for canons regular. The hospital continued to be held of the prior and abbot of Bermondsey, and in 1538 was valued by the visitors at 266l. 17s. 6d. It was surrendered to Henry VIII. in the thirtieth year of his reign.

Between 1540 and 1550 the citizens of London purchased the suppressed hospital, which was then vacant, from the crown, and repaired and adapted it for the reception of poor, lame, and diseased people; and in 1552 it was opened under the regulations detailed in a charter from the King.

By this charter, dated August 12, 1551, King Edward VI. considering the miserable condition of the poor, weak, and sick people, lying and begging in the highways and streets of London, to their no small grief and pain, and to the great infection and molestation of his subjects, and their health and security no less desiring than the curing and sustentation of the aforesaid poor, sick, and weak people, granted

to the mayor, commonalty, and citizens of the City of London, all the house and site late of the Hospital of Thomas Becket, in Southwark, lately called the Hospital of St. Thomas, in Southwark, and the church and all the precincts thereof. With these were granted also, the rectory of St. Thomas, and all the property in the parish of St. Thomas Becket, in Newington, in St. George's, Southwark, St. Saviour, and other parts, which had belonged to the late hospital, amounting to the clear annual value of 15*l.* 17*s.* 1*d.*, which the mayor, &c., and their successors for ever, were to hold by fealty only. The Hospital was now to be called the House of the Poor in Southwark, of the foundation of King Edward VI.; and the mayor, &c., from its funds were to provide two ministers for the parish and hospital church of St. Thomas, and two women or sisters to wait on the sick and poor in the Hospital; also one fit door-keeper to open the door to the poor there entering in and going out, and one apt and skillful surgeon to heal the sick and infirm in the said hospital, and one honest, sober, and pious man, who should be overseer and deputy of the mayor, &c., to oversee the Hospital, and to order and dispose of its revenues. He gave license also to any of his subjects to grant or devise, or sell, to the said mayor, &c., for the benefit of the Hospital, any property not exceeding the annual value of 46*l.*

In 1553, the property of the Hospital was again granted and secured to it by a charter appointing the common government of it and of Christ's and Bridewell Hospitals. Under this charter the corporation of the city were incorporated governors of all these three Hospitals, and empowered to act in all their affairs, and to make ordinances and appoint ministers or governors for their management.

In 1782, after disputes which had lasted many years between the corporation and certain other persons elected, and claiming to act as governors of the Hospitals, in virtue of donations made by them or otherwise, an arrangement or compromise was entered into and confirmed by Act of Parliament, under which the corporation of London have been since represented in the government of this Hospital by all the aldermen, for the time being, and twelve members of the common council appointed by that court. These governors are termed corporation governors.

In the period between 1553 and 1782 it appears that the Hospital was frequently embarrassed for want of sufficient funds, and was obliged to borrow from various sources; and this, although the property of the old Savoy Hospital founded by

Henry VII., which, in 1553, was conveyed to the corporation for the joint benefit of all the three hospitals, was, in 1562, granted to St. Thomas's alone. In time, however, gifts to a great amount were made by various private individuals to the support of this Hospital, and it was entirely relieved from its difficulties.

From these and from various other sources the annual revenue of the Hospital has now accumulated to the following amount:—

Rents of property in London, Southwark, and the suburbs of London, the greater part consisting of houses in various streets in the city, as the Old Bailey, Bow lane, Cheapside, and Paternoster-row, and in Wapping, Hackney, and the Borough in the neighbourhood of the Hospital	£13,962	1	0
Rents of estates in the country, situated for the most part in Buckinghamshire, Cambridgeshire, Derbyshire, Essex, and Middlesex	9,865	15	2
Annuities	142	6	8
Dividends of stock ..	671	10	8
Timber, average of ten years	236	6	0
From various other sources detailed in the report	879	14	2
	<u>£25,757</u>	<u>13</u>	<u>8</u>

The balance between several uncertain and casual receipts, and a number of yearly charges, more or less variable in amount, may be averaged at 526*l.* 6*s.* 6*d.* against the Hospital; deducting which, there remains for the general purposes of the Institution, 25,231*l.* 7*s.* 2*d.* Between 1780 and 1800 the rental increased 5000*l.* The majority of the building leases will fall in between 1860 and 1880, at which time a considerable increase of revenue is anticipated.

The total amount of personal property given by various donors for the general purposes of the Hospital, including the benefactions of donation governors, from 1693 to the commencement of 1837, is 184,378*l.*

The whole amount of the revenue, after deducting repairs, costs of new buildings, salaries of officers and servants, and other various contingent expenses, is spent in the care of about 46,700 sick and maimed poor annually, of whom about 3300 are admitted into the hospital, and are there provided with food, lodging, and attendance.

Among the disbursements of the funds, the most important are as follows, stating each nearly at the average of ten years from 1827 to 1836 inclusive:—

Repairs	£4500	0	0
Salaries and gratuities	4750	0	0
Malt and hops	880	0	0
Coals and wood	900	0	0
Furniture, bedding, &c.	800	0	0
Provisions	3700	0	0
Medicine and surgery	3500	0	0
Annual dinners	120	0	0
Stationery, &c.	125	0	0

The total amount of the expenditure in these years has varied from nearly 28,000*l.* to nearly 75,000*l.*, from the different amounts laid out in the purchase of estates and exchequer bills, and in defraying legal and other variable charges. In each year the balance remaining in the hands of the treasurer has been, on an average, about 1000*l.*

Government of the Hospital.—There are three kinds of governors; first, corporation governors; second, special governors, or governors by appointment, as they are here termed; third, donation governors.

The corporation governors are the lord mayor, the aldermen, and twelve members of the court of common council of the City of London. They have all the rights of other governors: if the Lord Mayor be present at a court, he takes the chair; and the president of the Hospital is always chosen from among the aldermen.

The special governors are appointed by the governors assembled at a general court, or by the standing committee subject to their approval. The appointment is made to scarcely any but retired officers of the Hospital, and to some of the executors of benefactors: they are not required to contribute any thing towards the funds of the establishment.

The donation governors are nominated by any governor in court or committee, and, if approved, acquire all the rights of governors by the payment of 50*l.* or upwards to the funds of the hospital. There is no limit to the number of this class of governors: they amount at present to 220; and no particular qualification is required of them.

With the exception of their share in the management of the institution, none of the governors receive any advantage from their office; and there is no ground for believing that any have made use of their privileges to obtain any personal advantage. The only instances in which articles have been supplied by governors, are those of the coals and some of the drugs, which are still furnished by parties who, after enjoying the custom of the hospital for several years, were subsequently made governors. The instances in which hospital property has been let to governors, are few and unimportant, and in all a full and fair rent is obtained.

The governing body of the hospital, or the body in which all power is vested in the last resort, is that of the governors in general court assembled. The executive or managing body, by whom almost all affairs are transacted in the first instance, subject to the control of the general court, is a standing committee, selected from the whole of the governors, and named the Grand Committee.

General courts are holden four times in every year, and at other times whenever special business requires. At these courts the steward, matron, and all other officers of higher rank, are appointed; and the proceedings of the grand committee are confirmed or amended.

The grand committee is composed of the president and treasurer, and thirty governors, who are elected for three years, and are ineligible for one year after their retirement. The members of this committee are appointed at the July general court, and at least ten members are elected in each year. The treasurer having struck out the names of those who have served their three years, or have not attended once in the course of the past year, selects, to fill the vacancies, those governors in preference who retired at the previous court, and then fills other vacancies with the names of other governors who are most likely to attend the meetings regularly. The treasurer's list is presented to the committee and to the general court, but is never altered by either of them.

The quorum of this committee is 5, and they meet on an average about once a month. They appoint the apothecary and some inferior officers, but the election of servants still inferior rests with the treasurer, who is also in the habit of directing all repairs of a trifling description to be done on his own authority. All the more important repairs and improvements in the hospital are performed under the sanction of the committee*.

Internal Regulation.

Patients, generally speaking, are received into the hospital on Tuesdays only; but accidents, and very urgent cases of any kind, are admitted at all times, and the urgency of the case may always be said to

* Here follows, in the Report, a remark similar to that which was quoted in reference to the extent of the powers exercised by the Treasurer of Guy's Hospital; and it is stated, that although these powers are somewhat greater than ought in strictness to be confided to any individual, yet the talents and long experience of Mr. Chapman, as well as the fairness and excellence of his administration, had contributed more to the benefit of the hospital than it might have received if the business which he constantly transacts had been placed under the management of any committee.

constitute the only claim to admission. A governor's recommendation has a preference only among cases of equal urgency, and for all other purposes it is entirely disregarded.

Any patient applying at the steward's office on a Tuesday, is provided with a petition, stating his age and disease, and he is sent with this to the taking-in room, where, according to the presumed nature of his case, he is examined either by the physician or the surgeon in attendance, who marks his petition so as to indicate to the steward how far the case merits or demands admission, and under whose care it should be placed. The patient then again goes to the steward's office, whence, in compliance with the mark of the medical officer, he is either dismissed or at once sent to one of the wards. If, among those who apply for admission, there are several more than can be admitted, whose cases are not of extreme urgency, but who all, in an equal degree, merit reception, a selection of a sufficient number to fill up all the vacant beds is made by lot; unless any of them have a governor's recommendation, and then these are first admitted, and the lots are drawn among the remainder. Except in these cases, a governor's letter is useless. No conditions of age, country, or character, are required; but it is usually demanded, except in cases of urgency, that some friend of the patient should engage to provide him with clean body-linen once a week, and to remove him from the hospital when required so to do. The cost of the former is 3d. or 4d. per week; and for the latter, in case of death, if the party giving the security will not bury the deceased, a guinea is demanded towards the expense of burial by the hospital.

Pauper patients are received like others, but the overseer of their parish is required to become their security for the engagements above mentioned, as well as for the payment of 9d. a-day to the hospital, for the patient's maintenance, so long as he remains in it. There is also a class called city patients, who are received on a requisition from the Lord Mayor or aldermen when sitting as justices; and another of Admiralty patients, who are admitted on the requisition of the physician-general of the navy. In each case it is usual for the requisitionists to supply the patients with clothes. A fee of 5s. is paid to the hospital on the admission of venereal parish patients; a fee of 3s. 6d. on that of clean city patients, and 10s. 6d. on that of venereal; and the same on that of Admiralty patients, who also pay 1s. on their discharge. The sums are paid for parish patients, by their respective parishes; for city patients, by the Chamberlain; and for

Admiralty patients, by the paymaster of the navy.

There are two exceptions to the admission of patients, founded on the nature of their diseases:—1st. Incurable cases are not received, except in those instances in which medical skill may ameliorate, if not cure, the sufferings of the patient; about twelve cases annually are discharged on this ground. 2dly. There is an old by-law, "That no person be received who is visited, or suspected to be visited, with the plague, itch, scald-head, or other infectious diseases; and if any such be taken in, then to be discharged as soon as discovered." This rule is not adhered to in any urgent cases, or in accidents.

In the year 1836, sixty-four patients were, on an average, taken in on each admission day.

The medical staff of the hospital consists of three physicians and three surgeons; one assistant-physician, one assistant-surgeon, a resident apothecary, an assistant-apothecary, a dispenser, and a surgeon-man.

The physicians and surgeons attend by rotation, so that one of each is at the hospital every day of the week except Sunday. Each surgeon appoints his own four dressers. The beds in the wards, with the exception of the accident and the convalescent wards, are divided among the several physicians as nearly equally as possible; each of the physicians having 55 beds, and each of the surgeons, on an average, about 93; making a total of 444, of which 75 are appropriated to venereal patients.

It is usual for the physician and surgeon in attendance on the general admission day, to select from among the patients those whom they chiefly wish to have under their own care, and having with these filled all the beds that are vacant in their own wards, then to select those which are best fitted to fill the vacant beds of their colleagues. Accidents are admitted at all times, and are placed in one of the accident wards (of which there are two). Each case is immediately attended to by the dresser of the ward, who resides in the hospital, and is in constant attendance, and has usually another dresser with him, to act as assistant in case additional aid should be required. It is the duty of the assistant-surgeon to attend on all accident-cases whenever he may be called upon by the dresser of the week, and to operate whenever, in his judgment, an operation is required.

The visit of the medical officers is usually at one o'clock. The prescribed number of visits for each, is two in the week, but they are actually always more numerous, and are often made daily. Each visit usually occupies from an hour and a half

to three hours. When one of the principal physicians or surgeons obtains temporary leave of absence from the hospital, his place is for the time supplied by the assistant.

The duty of seeing and prescribing for all the medical in patients, on those days on which the physician or assistant-physician does not visit them, devolves on the resident apothecary, who thus takes charge of all patients not affected with chronic diseases. He goes round the hospital every morning, from half-past ten to one, and every night, between half-past eight and ten; and visits the more important cases as often as is deemed necessary. He also prescribes, in the first instance, for all such surgical cases as require medical attendance; and he is at once called in in every case of emergency. Besides these duties, he has to provide the necessary drugs and medicines for the consumption of the hospital; all of which are entirely under his control, and are ordered on his own responsibility. None of these are supplied by contract.

On the days of the non-attendance of any of the surgeons, his patients are attended to by one of his four dressers, who, in any case of emergency, sends for the assistant-surgeon, who is, for this reason, always required to reside in the immediate neighbourhood of the hospital. The rotation of duty among the dressers is as follows:—A dresser, on the taking-in day of his surgeon, takes charge of all the cases admitted by the latter into his own beds, and of all accidents during the week. During the next two weeks, he takes all the cases admitted into his principal's beds by the other two surgeons. The fourth week is again the taking-in week of his principal, and then another of his four dressers becomes dresser of the week, and goes through the same cycle.

The regular day for the performance of operations is Friday.

The constant and immediate charge of the patients is confided to the head nurses, or sisters; of which there is one to each of the 19 wards, and on whom the whole management of the ward depends. The sisters are now never selected from among the nurses; it has been found more advisable to choose them from among the class of shopkeepers or head-servants in gentlemen's families, than to promote the nurses who are subordinate to them.

To each ward there is one day nurse and one night nurse, or watcher.

The out-patients are under the care of the assistant physician and the assistant surgeon; the former of whom attends on the Tuesdays and Thursdays; the latter, on the Mondays and Wednesdays in every week. Persons desirous of becoming out-

patients, obtain letters by applying at the steward's office, which letters are required to be renewed after the patient has attended four times. In practice, however, these regulations are not strictly attended to; for whenever any one requiring assistance applies for it without a letter or ticket, the medical officer fills up the necessary form and prescribes for him at once. In all urgent cases the patients are desired to attend on more than the usual days, that they may be seen by their medical officer or by the apothecary; or, if necessary, they are at once, or at some early period, received into the hospital on the recommendation of the officer under whose care they are placed as out-patients. The assistant physician is usually occupied on each of his days of attendance from 11 till half past 3 or 4. The assistant surgeon sees, on an average, 350 patients in each week.

Besides these two classes of out-patients, some others are seen and prescribed for by the apothecary at his shop, and others, by the dressers on the days on which the medical officers are not in attendance. Advice is also given to midwifery out-patients by the lecturer on midwifery; and women in labour are attended at their own houses. The midwifery patients attend on Fridays.

The total number of cases treated in 1836, (a year in which, however, the number was more than one-fourth more than the average of the nine preceding years), was 46,674: of these there were

Patients discharged from the	
Hospital	3,025
Physician's (assistant) out-patients ..	11,404
Surgeon's (assistant) out-patients ..	19,870*
Midwifery out patients (including 151 women attended at their homes during confinement)	1,451
Apothecary's out-patients	5,965
In-patients died during the year	298
Do. under cure, 31st December, 1836	428
Out patients under treatment, physicians'	302
Ditto, surgeons'	800

Medical officers and School.—The three physicians and three surgeons receive from the Hospital funds a salary of 40*l.* a year each, a remuneration manifestly very in-

* In this class, each patient is reckoned as a new patient each time of his attendance, and every casualty, of whatever kind, is included.

adequate for the services they perform. The institution of a medical school, in connexion with the Hospital, has the effect of adding to the emoluments of the medical officers; of furnishing, through the medium of the pupils, additional and gratuitous medical attendance on the Hospital patients; and, lastly, of imparting a medical education to the pupils themselves by lectures, illustrated during their personal attendance on the patients by observation of disease, and of the results of treatment. The emoluments arising from the pupils' fees for attendance on hospital practice, averaged, for the ten years preceding the inquiry, for each physician, 199*l.* 9*s.*; and for each surgeon (including the 200*l.* paid by his dressers), 448*l.* 3*s.* 6*d.*

The apothecary receives from the Hospital funds a salary of 300*l.* out of which he has to pay an assistant 50*l.* He receives also a guinea for each pupil who enters to the medical practice, and shares equally with the surgeons in the fees for attendance on the surgical practice: he receives also some small share of the fees paid by dressers, and of the payments of each pupil on entering to any course of lectures, which, altogether, makes his average income, during the last ten years, 644*l.* He has also a house provided for him in the Hospital, and is allowed to take an unlimited number of apprentices, but is debarred from private practice. The assistant apothecary receives 50*l.* a year from the apothecary, and 50*l.* from the Hospital funds. The assistant physician receives nothing for his services. The assistant surgeon has a sum of 150*l.* yearly towards the rent of his house, which is required to be in the vicinity of the Hospital.

The dressers are selected by the principal surgeons, and each pays a fee of 50*l.*, if he enters for a whole year, and of 30 guineas if for six months only. They are recommended to attend the hospital practice for six months previous to commencing their duties. They usually "take their box," (as this is termed), at the end of their second year of study in the school. Their duties are similar to those of dressers at the other hospitals; and each has, for his own week, to perform the duties which in some hospitals devolve upon the house-surgeon.

The appointment of the physicians and surgeons, and the assistants, are made by the general court; and those of the apothecary and his assistant by the committee. With reference to the former, it is remarked (and this remark is of course intended to be applied to the same system of election in the other large hospitals,) that many of those who vote are doubtless sensible of the weighty responsi-

bility they are under to avail themselves of all means within their power of ascertaining the respective merits of the several candidates; but when we consider that the far greater part of the governors cannot themselves possess the knowledge requisite to decide on the relative competency of the rival candidates, and have not the leisure nor the opportunity to obtain it; that, conscious of their incapacity in this respect, they are probably guided in the matter by the opinion of the treasurer, or some other influential governor, if not by personal favour or connection; and that the task of selection being entrusted to many, the responsibility is so divided as to have little influence on the result, it will not be thought extraordinary that, though no evidence whatever was adduced, nor, indeed, was likely to be adduced, of the election of absolutely incompetent and unskilful persons to fill these situations, the medical officers examined were almost unanimous in opinion that an alteration in the mode of election would be a material improvement in hospital administration. A difference of opinion prevailed as to the kind of change that was advisable; some thought that the French system of *concours* itself might be advantageously introduced, at least in the election of lecturers (who are now appointed by the treasurer, on the recommendation nominally of the medical officers, but sometimes without even that), and that all hospital appointments whatever should be made only after an efficient examination, according to the French system, in public. Some were decidedly of opinion that all hospital appointments should be upon a public competition, open to all persons possessing certain qualifications, and that the candidates should be examined by a board composed of the principal physicians or principal surgeons (as the case might be) of all the London hospitals; others suggested, as a great improvement on the present system, that all such appointments should be made by a medical council, composed of the medical officers of the hospital in which the vacancy existed, and of some other London hospital; or, at least, that such a council should possess the power of nominating two or three parties, from whom the governors themselves might make their own selection.

Such alterations as these, however valuable, are not likely to be adopted voluntarily by the governors; and if thought to form a proper subject for the interposition of the legislature, should perhaps be considered only as part of a more extensive plan for the improvement of the management of these institutions, and the advancement of medical science.

With respect to the appointment of

dressers, who are chosen by the surgeons from among any who enter their names for the office, and not merely on account of their superior qualifications, it is said—These circumstances appear to give weight to the opinion, that the dresserships at least should be open to public competition; that certain qualifications should be required; and that the candidates should be publicly examined by competent parties.

The other officers of this hospital are—the treasurer (Abel Chapman, Esq.); he has a house in the hospital, but no salary; he exercises a general control and superintendence over the hospital, and all the officers and servants, and may be considered in this respect as the executive officer of the committee.

The minister, who is the parish priest of St. Thomas's; and the chaplain or hospitalier (the Rev. J. Tuson), whose duties are entirely confined to the chapel and hospital wards, and who has no other spiritual charge, nor any connected with the parish or parish church of St. Thomas.

The law-clerk, Mr. R. A. Wainwright, acts as secretary and solicitor to the hospital. The steward, Mr. W. Nash, has the whole internal management of the establishment, and the superintendence of the subordinate officers and servants, and all workmen employed within the building. The matron, Mrs. Savory, has the general superintendence of the female wards, and of the sisters and nurses, the former of whom she selects for the approval of the treasurer, and the latter of whom she appoints, and if necessary dismisses, herself. The receiver or accountant of the hospital, Mr. M. Ledger, receives and pays all money under the direction of the treasurer, and keeps the accounts of the hospital. The architect and surveyor, Mr. J. Field, has the charge of all the property in London and the neighbourhood. There are also a butler, cook, baker and assistant-baker, and porters.

Of the sisters of the wards, four receive 50l. a year each, and fifteen have 37l. a year. Of the day-nurses, five are paid 27l. a year each, and thirteen, 25l. Of the night-nurses, or watches, the salaries are for six, 22l. 2s. a year each; and for fourteen, 19l. 10s. each.

The report concludes—It is not to be denied that the general application of the funds, and the management of the hospital, are highly creditable to the authorities to whom they are entrusted, and that the benefits which the charity in its present state confers on the poorer classes of the community are very great. Such defects as exist appear to us to be incidental to the system rather than chargeable on the individuals by whom it is administered;

but while we feel that an alteration in the constitution of the governing body, and other matters connected with the improvement of this and similar institutions, may well deserve the attention of the legislature, we do not consider it within our province to suggest the precise amount or nature of the alterations requisite.

CAUSES OF THE SOUNDS OF THE HEART.

To the Editor of the Medical Gazette.

SIR,

PERMIT me to bring before the notice of your readers a physiological subject which is highly interesting, on account of its value in diagnosis. My object is to prove, that the sounds of the heart are caused by the valves, and the valves only; the question is still *sub-judice*; at least I have met with no public acknowledgment of the truth of my proposition, published in 1832, that the normal sounds of the heart are produced by, and depend upon, the tension of the valves.

The moment I read Laennec's assertion, that the second sound was caused by the auricles, I perceived that it was erroneous, as being inconsistent with the successive actions of the heart, acknowledged by physiologists from the time of Haller, and fully confirmed by experiments on animals, viz. that the auricles contract first, then, following continuously without any interval, the ventricles, and that subsequently there is a period of relaxation, or cessation of action, in each part, during the diastole,* between each systole. I was thus satisfied (from the repose of the muscle,) of the *impossibility* of the auricles having anything to do with the second sound, there being no action of either auricles or ventricles going on at the moment, for it was the time of relaxation of both.

Dr. Hope, in his first edition, p. 49, endeavoured to prove that this sound was produced by the "ventricular diastole," and "the blood shooting with instantaneous velocity from the auricles into the ventricles;" although, as he set out with acknowledging that the second

* During the diastole, the muscles are flabby, and yield to the pressure of a probe, whilst during systole they are felt to resist or rather repulse it. The heart being a forcing pump it is merely necessary to apply one hand over it, and the other to the pulse, to be satisfied that the beat of the heart ("impulsion") depends upon the firm bulging of the muscles in systole.

found takes place at the moment that the auricle is relaxed, the blood at that time could be only flowing into the ventricle gently, from the veins, through the auricles, as it always does at that time; for the ventricles are partly filled in this way, before the auricles (which are never empty) inject the blood into them, so as to stimulate them.

It was evident to me that there was no cause in existence at the moment to produce the sound, except the tympanic collision of the ventriculo-arterial (sigmoid) valves; or in other words that the sound was entirely valvular; and having established that cause as "sufficient" for the second sound, I ventured (upon the Newtonian principle) to assert it as the cause of the first sound, and can prove it to be so, the difference in form of the auriculo-ventricular valves and surrounding attachments accounting for the slight difference in duration and tone of the sounds.

These opinions, which I had discussed with friends and pupils, appeared to me such self-evident propositions, that, until I found Dr. Hope and others labouring to establish erroneous explanations, I did not think it necessary to publish mine. At last I made them the subject of a communication to the Hunterian Society, 9th Feb., 1832, together with some practical observations, to show that pathological alterations confirmed my explanation; this was published in the *Lancet*, 19th May, 1832, and afterwards in the *Med. Chir. Review*.

Dr. Hope instituted a number of experiments, as is well known, with the endeavour to support his opinion, that both the first and second sounds were caused by the "motion of the contained fluids," "the vibratory collision thus occasioned amongst the particles of blood producing sound." This cause, however, he relinquished for the "bruit musculaire;" and at last he was compelled to acknowledge, in his Appendix, 1835, that the cause of the first sound might be "possibly partly valvular."

In the new edition of his work, published last year, he still adheres to the opinion of 1835, except that he quite acknowledges that the first sound is not merely "possibly," but actually partly valvular; but he coincides with the opinion of the London Committee of the British Association for the Promotion of Science, respecting bruit musculaire.

Now I contend that the first sound, as

well as the second, is entirely valvular, and deny that any part depends upon muscular noise, ("bruit musculaire") for when there is simple hypertrophy (increase of muscle and muscular action,) there is diminution of sound, although more of the condition necessary to bruit musculaire: this contradicts his opinion and confirms mine, inasmuch as it is the valves being encroached upon, and their having less blood to stretch them, which prevents their producing the usual sound. Again, when there is moderate hypertrophy, with proportionate dilatation, there is not appreciable increase of sound, though, if he were right, the quantity of muscle being increased, there ought to be increase of sound. My explanation accounts for the sound here remaining the same, as the valves are in their usual relative condition. Again when the heart is enormously enlarged by hypertrophy and dilatation, in which case there ought to be enormous first sound (if bruit musculaire were a cause) there is none, or scarcely any, because the openings are so dilated that the valves cannot act: thus we have pathological confirmations of my opinion.

In his last edition, 1839, he endeavours to shew that he was not ignorant of the valvular theory in 1830. He does not, however, understand it yet; he speaks of the valvularity of the second sound being confirmed by his experiments, as if he had not been labouring to upset it by his experiments, and as if I had not published the valvular theory in opposition to him, when he was experimenting to establish the erroneous hypothesis which he afterwards relinquished: his successive publications prove the fact. He says (page 13). "that the sound was *not* attributable to the retrocession of the semilunar valves, I entertained a strong presumption." What was to have prevented him as well as myself from having a perfect certainty that it *was*?

I proved the *impossibility* that the second sound could proceed from any other cause than the valves, and Dr. Hope had exactly the same data to reason upon.

In his chapter headed "ERRONEOUS THEORIES," Dr. H. states that my theory of the first sound was imperfect, because I do not add the bruit musculaire: this I deny: the valvular "cause" is "sufficient." I have accounted for the differ-

ence of sound by the difference of shape of the auriculo-ventricular valves; their attachments are different, they are set in stronger rims, the sigmoid valves are merely attached in a tube, as it were, whereas the auriculo-ventricular have a firmer and different attachment to the parietes of the ventricle, which being in systole at the time of tension, altogether a flatter and longer tone is produced. Again, and above all, there is no sound when there is plenty of muscular action from hypertrophy, because the valves cannot act; hence necessarily it is the valves, not the muscles, which produce sound.

Having been the first to publish the valvular explanation of the sounds, I am bound to confute the assertion of Dr. Williams, "that I hold the same opinion as that in print by Dr. Elliott, and of which he says I was a *later* advocate;"* the fact being, that I proved the second sound to depend on the *tension* of the *valves*, produced by the backward pressure of the blood from the *arteries*; whereas Dr. Elliott asserts, that the second sound depends upon the *blood flowing* from the *auricles*, which he even puts in italics; so that my demonstration is, that the sound is caused by the *valves* in *holding* the blood on one side of the heart, whilst the "opinion" of Dr. E., on the contrary, is, that it is caused by the *blood flowing* in on the opposite side, and he uses the word "verrit" as expressive of the sound produced by sweeping or brushing along. Again, so far from attributing the second sound to anything but the rushing of the blood, he (following Dr. Hope) attributes the sudden nature of that sound to the rapid and vehement (as if relaxation could be vehement) diastole of the ventricle; and its abrupt termination ("*abruptum*" in italics) to the instantaneous impediment which the sigmoid valves offer to that motion of blood to which alone he refers sound: thus the only allusion he makes to the valves is, not as producing, but as cutting short the sound, and so far from considering the valves to be the cause of sound, he is evidently puzzled, (as we may infer from the expression "fatendum est,") to account for the sound ceasing when it does, "though the blood continues to flow into the ventricles

after the sound has stopped," which my explanation of valvular sound renders perfectly clear: the passage shews that he looked only to the flow of the blood, and not the valves, as the cause of the sound. In fact, so far from originating the opinion of the sound depending on the valves, he does not advance that as his opinion, and in his thesis there is no originality, but a professed compilation and adoption of the opinions of others—Hope, Williams, &c.

The following is the passage from Dr. Elliott's thesis:—"Nobis igitur (me iudice) concludendum est, sanguinem a ventriculis agitatum et in arterias immisum, primum sonum cordis efficere: secundumque a sanguine pendere in ventriculos, dum horum fit diastole, ex *auriculis* influente. Hoc plane confirmatur a phænomenis quæ in vitis valvularum cordis observantur. Naturam soni secundi *subitam* et *abruptum* oriri credo a diastole ventriculorum tam repente et vehementer inchoatâ ut sanguis vi magnâ auricularum parietes transcurrat: nec non ab impedimento quod in corpore sano fere instantur valvulæ præstant sigmoidæ sanguini, qui in ventriculos, dum horum fit diastole, ex arteriis vult refluere. Post sonum secundum quidem fatendum est adhuc plus sanguinis ventriculos inire: hic autem, ut annotat Hope, ventriculorum parietes (jam multo fluido distentos nec ultra ab illo fricatos) haud verrit, sed cum sanguine jam illic congesto, sese in silentio commisceet nec aliquid interea soni ab auriculis editur, quippe quæ sanguinem quem impellunt accurate usque sequuntur. Motum igitur sanguinis, tam a diastole quam a systole ventriculorum effectum, sonorum cordis præcipuam esse causam erendum est: quod ab observationibus quibusdam Doctorum Bertin, Williams, et Hope, singulari in modo confirmatur.

The London Committee of the British Association, appointed to investigate and report upon the subject, appear to agree with me as to the second sound, but make the unphilosophical addition of bruit musculaire to the true cause of the first. (See Med. Gazette, Dec. 10, 1836, and Dec. 2, 1837.) I say they appear to agree with me, so far as acknowledging the valves to be the cause of sound, but they do not seem to understand the true principle, which is, that it is the tympanic tension which produces the sound. I judge from the

* Lectures on the Physiology and Diseases of the Chest, &c. &c. By Charles J. B. Williams, M.D., F.R.S.—Medical Gazette, July 1838.

expression in the report, that "it is impossible that the auriculo-ventricular valves should close with a *flap* in the same way as the sigmoid valves." They speak as if the surfaces of the valves flapping together produced the sound, like the click of a solid valve, and Dr. Todd, one of the committee, in republishing this opinion in the *Cyclopædia of Anatomy and Physiology*, (article Heart, p. 616,) misrepresents my statement, saying that the first sound is referred by me to the rapid *approximation* of the auriculo-ventricular valves; than which nothing is farther from my opinion, which is, that both first and second sounds depend solely on valvular tension, and he gives his own version, not a translation of the above passage, in Dr. Elliott's thesis, referred to by Dr. Williams, his colleague in the last committee.

I will not attempt to take up any more space of your valuable journal by repeating arguments respecting the circulation, &c., or the true cause of impulsion, which I have published elsewhere (vide my *Principles of Medicine*, &c.), in opposition to errors arising from their authors having neglected to make themselves acquainted with the very rudiments of physics. A correct knowledge of the nature of the normal sounds of the heart is of the utmost consequence to diagnosis, inasmuch as every aberration is the more easily detected and accounted for. I have read that, through pathological observations, Dr. Carswell arrived at the same opinion as myself respecting the second sound; the road, though circuitous, led to the truth, and I feel happy to have the concurrent testimony of a person of such acknowledged talent.

I have the honor to be, sir,
Your obedient servant,
A. BILLING.

Bedford Place, 20th March, 1840.

NEW OXYHYDROCARBON.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of communicating the properties of a new *oxyhydrocarbon*.

Some time since I had given me by Mr. Whipple, chemist to the firm of

Barron and Co., a specimen of a crystalline matter which was spontaneously deposited from the essential oil of bitter almonds. Mr. Whipple not having before observed such a deposition, regarded it as an extraordinary product, and sent a sample to Professor Faraday, who thought it might be benzoic acid. On examination, however, I find it to be a new compound of oxygen, hydrogen, nitrogen, and carbon. The following are a few of its properties:—

It occurs in small acicular crystals of a bright straw yellow colour, having the odour of bitter almonds, and are free from taste. When heated they fuse, but are not sublimed, producing an amber-coloured oily liquid; heated to redness they are decomposed, leaving a carbonaceous residue. The crystals are perfectly insoluble in water, alcohol, or ether, whether cold or boiling. Boiled in dilute nitric acid they dissolve, forming a solution which is precipitated yellow by ammonia, and yellowish white by tannic acid. Strong sulphuric acid forms with them an orange yellow solution, precipitated yellow by alkalis, and is rendered carmine red by the salts of iron. Boiled with a solution of perchloride of iron, there is produced a carmine red liquid. Heated with potash they do not give out ammonia.

By their insolubility in alcohol, and non-susceptibility of sublimation, they are at once distinguished from all the substances likely to be met with under these circumstances—viz. amygdaline, benzoic acid, benzamide, and benzoin. Its characteristics are its being rendered orange yellow by sulphuric acid, and carmine red with perchloride of iron.

It appears to be a compound of carbon, hydrogen, oxygen, and nitrogen, united so as to form a bicyanide of benzule, and is produced by the oxydation of the hydrogen of two equivalents of hydrocyanic acid and the one of hyduret of benzule of the oil of bitter almonds; its symbol, therefore, will be, $Cy^2 + Bz$; and equivalent, 157.

I am, sir,
Your obedient servant,
H. LETHEBY.

116, Britannia Street.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

On the Influence of Artificial Light in causing Impaired Vision, and on some methods of Preventing or Lessening its injurious Action on the Eye. By JAMES HUNTER, M.D. Surgeon to the Eye Dispensary of Edinburgh. Edinburgh, London, and Glasgow, 1840. 8vo. pp. 94 and a plate.

ONE of the first effects of the improper use of artificial light, says Dr. Hunter, is sub-acute or chronic inflammation of the lining membrane of the eyelids. The next symptoms are those of incipient amaurosis; and two-thirds of the cases of this disease “occur in those who use their eyes very much by artificial light, particularly persons belonging to the following classes of society:—1. Literary men, students, clerks, transcribers, composers, and others much engaged in reading or writing at night. 2. Tailors, sempstresses, and shoemakers. These persons generally work late at night, and often are obliged to use artificial light, even in the day time, in consequence of the frequently obscure, and almost under-ground situation of their places of business, which often are very ill ventilated, and oppressively warm. 3. Engineers, stokers, enamellers, glassblowers, and other persons much exposed to the combined action of intense light and heat,” p. 24.

But why is the light of candles more injurious than the rays of the sun? This question is answered by our author in his second chapter.

Newton showed that a beam of white light might be divided into seven prismatic colours of red, orange, yellow, green, blue, indigo, and violet, but more recent experiments have shown that there are only three primitive colours, namely, red, yellow, and blue; the others being formed by mixtures of these. Mr. Field has found that a beam of day-light is composed of red, yellow, and blue rays, in the several proportions of 5, 3, and 8. “The heating power of light varies with the colour of it, as is shewn in the following table by Sir Henry Englefield, which exhibits the heights of thermometers placed in the different rays composing a beam of white light.

	Rays.	Degrees Fahr.
In the	{ Blue,	{ 56
	{ Yellow,	{ 62
	{ Red,	{ 72
	the thermometer stood at	

Therefore artificial light, by containing an excess of red and yellow rays, will have a greater primary heating effect in proportion to the illuminating power of it than common day-light.” p. 38.

On the other hand, “In common artificial light there always is an excess of the yellow and of the red rays, which give it more or less of an orange or yellow colour, according to the way in which the light is arranged, and according to the substances from which it is procured. The purest ordinary artificial light is obtained from different materials in nearly the following order. Oil-gas—Naphtha—Sperm-oil—Coal-gas from the best parrot-coal—Wax, Spermaceti, and Stearine Candles—Vegetable Oils—Moulded Tallow Candles—Coal-gas from inferior coal, such as is used in London—Course Oils and Dipped Tallow Candles.” p. 31.

This excess of red and yellow rays injures the retina, and it “becomes less sensible to those rays that are in excess, so that afterwards, when it views a white object by daylight, the blue rays contained in the white light reflected from the surface of it make a greater impression than the red and the yellow rays, and the object appears more or less of a dingy blue or purple colour, as illustrated by the experiment described in the introductory part of this treatise. This dark blue or purple tinge is *complementary* to the orange or yellow colour of the artificial light.

One colour is said to be *complementary* to another, when the addition of it to the latter completes the chromatic triad necessary to form white light. Thus, green is complementary to red, because green is composed of yellow and blue, which united to red make white light; so blue is complementary to orange, which is composed of red and yellow; and purple, which is formed by a mixture of red and blue, is complementary to yellow. Whenever the eye is long exposed to light of one colour, it becomes partially insensible to it, and sees the opposite or complementary colour. Thus, if a person look at the sun through a dark blue glass, and then regard a white surface, it will appear

orange; had the glass been red, the surface would have appeared green, or green if the glass had been red, and so on. * * * Although all kinds of coloured light may prove injurious to the eye by stimulating it unequally, some are much more hurtful than others. An excess of blue light is least injurious; then bluish green, green, yellowish-green, yellow, orange, and red, in the order here given. In good artificial light, the yellow rays are in much greater excess than the red ones; but, on the other hand, the red rays are comparatively more hurtful, in consequence of their greater force and heating power." p. 35.

But besides the injury caused by the defective chromatic composition of artificial light, its indirect heating power, the carbonic acid gas which is formed during its combustion, and its unsteadiness, and generally bad position, add to its destructive force.

The third chapter contains the prognosis and treatment of amaurosis; they are somewhat scantily given, as the book is intended for the public, but are good as far as they go.

In the fourth chapter Dr. H. treats of the choice of artificial light. He discusses the comparative advantages of olefiant gas, naphtha, oil-gas, parrot and cannel coal-gas, sperm and fine oils, Parker's hot oil-lamp, wax and other other candles, and Palmer's candle-lamps. The first on the list is the best, but is too expensive for ordinary use. Our author approves of the light of gas, provided the gas is made as at Edinburgh, of parrot or cannel coal, and not, as in London, of common coal. He allows that gas-light has done more injury to the eyes of thousands than any other kind of light, from the enormous quantity in which it is used, "producing a flood of light in the remotest corners of apartments (where the sight is to be exerted on fine work, for hours at a time, and night after night), where there is hardly so much as a single shady spot towards which the exhausted eyes can be turned for relief during any temporary relaxation; whilst at the same time, it heats the surrounding air to a most injurious degree, and poisons it with carbonic acid. Thus the cheapness of gas-light leads to its abuse; but its other advantages, viz. the facility with which it may be placed in any re-

quired position, and increased or diminished in intensity according to the nature of the work, are also too often abused; by having the light placed close to the eyes, without any opaque shade to intercept the extraneous rays that obscure the distinctness of the picture on the retina; or by employing a stronger and stronger light in proportion as the sensibility of the optic nerves becomes impaired, to obtain a present, though temporary relief, with the certainty of ultimate permanent injury to the sight." p. 71.

Chapter the fifth and last treats of the prevention of the injurious action of artificial light. For this purpose four expedients are recommended. The *first* is that of improving the colour of the light by adding the primary rays which are deficient, or absorbing those which are in excess. Thus, a conical reflector, the inside of which is painted of a sky-blue colour, may be placed over the light; or the light may be transmitted through a solid or fluid medium of a pale blue colour. The former of these methods is the best; and a mixture of ultra-marine and Prussian blue gives the necessary tint to the reflecting surface. Blue spectacles are not to be recommended; "as, from the greater warmth of the absorbed rays, they become hot and uncomfortable; and, from the loss of light they occasion, they require to be removed when the eye is turned for a moment to any other object than that on which the light is concentrated." p. 76.

But supposing that the person was obliged before to wear spectacles to aid his sight, it seems to us that theoretically the addition of the blue tint ought to cool the hot red and yellow rays as they pass through.

The *second* is to diminish the heating effect of artificial light by making its rays pass through water. This is to be done chiefly when a very strong light is required, as in engraving. The dryness of the air caused by combustion is to be obviated by ventilation, and, in some cases, by evaporation of water.

The *third* expedient is to prevent the bad effects of the carbonic acid gas by proper ventilation, and by regulating the combustion so as to obtain the greatest intensity of light with the smallest consumption of materials. When many persons are crowded into a small space,

with much artificial light "great advantage is derived from having a metal tube with a funnel-shaped extremity placed over the lights, as represented in fig. 3, and communicating either with the open air, or with a chimney. By such an arrangement the carbonic is removed as soon as it is formed, and the air of the apartment kept cool and comfortable, especially if care be had to enclose the ventilating tube in a case of wood or leather, or some other bad conductor of heat." p. 84.

The *fourth* expedient is to use shades. They may be attached to the light, or worn by the person whose eyes need protection. The former method is to be preferred. Our author does not agree with Sir David Brewster that ground glass shades are actually hurtful, but thinks that their advantages as a protection to the eye are greatly overrated. When the light hangs from the ceiling, about forty degrees above the eyes, no opaque shade is required. "But when the light is placed lower down, as when a common table lamp is used, the eyes of those sitting round it should be protected by having a shade of some opaque substance in the form of a circular band, of about four inches in breadth, placed round the circumference of the ground glass moon, as recommended by Dr. Arnot; and which allows a brilliant light to fall on the table, whilst the rays that pass upwards to the ceiling and upper part of the walls being reflected, diffuse a sufficient and very agreeable light in the rest of the room." p. 88.

After all, however, the best way of preserving the eyes is to adopt a more rational system of life. "This is a subject that is too little attended to at present; for the very late hours to which shops and other places of business are kept open; the ridiculously late period of the night to which our public amusements are protracted; with the bad example of our legislative assemblies sitting in debate till long after midnight; are customs which being productive of much evil, should be discouraged as much as possible." p. 89.

Dr. Hunter's Essay is very useful, and though written for the public, will be advantageously consulted by medical practitioners.

MEDICAL GAZETTE.

Friday, April 3, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso." CICERO.

INSTITUTIONS FOR SPECIAL DISEASES.

It is evident that two widely different principles prevail among the members of the profession with respect to the method in which its multifarious labours should be divided; and of these the one is entirely practical, the other as eminently theoretical. While one party are daily lauding and endeavouring to propagate their opinion, that all distinctions should be merged in one single Faculty, of which every member's acquirements should be as multiform as their diplomas were simple and uniform, another are daily adding to the list of those who step from the general wide paths of professional practice, to cultivate and reap the profits of some single little tract, to which, by its real or apparent degree of fertility and usefulness, they may attract the attention of the public.

Neither of these parties, indeed, includes much more than a small portion of the profession, though, strange as it may seem, a few members are advocates of the principles of both; theoretically upholding the propriety of a single faculty, while they practically support the most minute division of professional labours. It is not our purpose at present to consider the question of the fusion of medical distinctions, for it has already occupied our attention on several occasions, and on the whole the present prospects of its advocates are not such as to give its opponents any cause for anxiety. We propose, however, briefly to consider the practice which is now so extensively prevalent, and apparently

increasing, of separating from the general practice of the profession, or of any of its main branches, to pursue some single object—the diseases of some one organ, or of some one class or nosological division; and by the erection of special hospitals or infirmaries for the patients of that one favoured disorder, to obtain an undue share of public attention and sympathy for them, and ultimately (that which often too evidently forms their main object) a monopoly of public patronage for the originators of the schemes.

There are evidently certain maladies which it is not only fair, but useful or necessary, to make the subject of special and almost entire study. Mental diseases are usually regarded as such, the custom of the profession having long consigned them, whenever it has been possible, to the charge of the few who will devote their whole time and attention to their management. In like manner the peculiar nature of their disease renders the exclusion of lunatics from general hospitals in the highest degree desirable; and special institutions for their care must ever be objects deserving a large share of public support. Reasons scarcely less cogent will fully authorize the establishment of hospitals for some distinctly contagious diseases, as small-pox. But as to typhus, we must say that except on the occasion of an unusually extensive epidemic, in which the cases would be so numerous in the general hospitals as to endanger the rest of the patients, we are far from convinced of the necessity, or even of the utility, of separate establishments.

A class scarcely less requiring special consideration are obstetric cases; and for these the usual customs of the several lying-in hospitals and dispensaries, with which attendance on lying-in women at their own houses is conjoined, accomplish that which the best

judgment might have suggested as most desirable. It is gratifying also to observe, that (as far as our own knowledge extends) the officers of all these establishments are gentlemen fully calculated, by a general medical education, for the charge which they undertake—a charge which, however natural the process that they have to superintend may be, can rarely be held with safety, in the artificial state in which we live, by any one unacquainted with disease.

Next to these, as justifiable objects of special support and special professional study, we would place the diseases of the eyes; for in these, though they perhaps require, more than either of the preceding classes do, a nice and profound knowledge of the general principles of medicine and surgery, there is often required, besides this, an amount of tact and manual dexterity which few who obtain their experience of ophthalmic surgery only in the chances of common and general practice, can hope to attain. Besides, it both was, and is still, essential to give some peculiar encouragement and opportunity for the study of the diseases of the eye by professed general surgeons, in order to prevent them from becoming a monopolized field for non-surgical oculists; than whom, in the general, no more mischievous class of unauthorized practitioners can be found upon the borders of our territory. One can, probably, nowhere find a more marked example of the greater benefit that results from the grafting of these particular branches upon the great trunk of medical science, instead of endeavouring to plant them as slips and nurture them even in the most favourable soils, than we find in a comparison of the works of the surgeon-oculists of this and of other countries with those of the oculists not surgeons. The one have made this branch of surgery the first and fairest of the

whole; the others are but useless to the world and disgraceful to their authors, teaching nothing but how vain it is for any one to give even all his time and (it may by accident be) his talents, to the detail of any subject of which he is totally ignorant of the general principles.

We should be glad if we could find as much cause for approbation in regard to the separation of the treatment of affections of the ear, for which, in many respects, the same claims might be made as for those of the eye; and for which it might especially be urged, that a cultivation of them by accomplished practitioners would tend to withdraw their management from the hands of some by whom the science is neither honoured nor improved. There can be little doubt that a cultivation of the surgery of the ear, by the same class of persons as have so exalted the science of ophthalmic diseases, would rapidly tend to bring it from the darkness by which it is still obscured, notwithstanding the great advance that it has made by legitimate means within the last few years. But this, we feel assured, can never be effected, except by those who are strictly, and in the full meaning of the term, medical practitioners.

But here we believe the list of justifiable separations must be closed; it includes, we think, all the diseases to which any physician or surgeon can, with propriety, give his sole attention, and certainly all for which he can, with any justice, require the public to support special charitable institutions. As far as we know, the only claims that can be made for special provision for any disease, are either that those who suffer from it are excluded from general hospitals, or that they require the knowledge of practitioners of peculiar experience, or that in general hospitals their treatment is not considered suffi-

ciently important or interesting. By the first circumstance, maniacs and obstetric patients demand peculiar assistance; and besides these, there are a few other diseases—as venereal affections—for which, as it is the custom in some of the hospitals of the metropolis, to exclude these subjects from their wards, the Lock Hospital is not less justifiable than necessary. But for what other class, among the many for which separate hospitals are now got up, can any claim be made on this ground? Certainly it might be fairly urged for bad legs, with which few hospital surgeons are anxious to fill their beds, and with which hundreds of sufferers are therefore compelled to remain unassisted, and uncured, for the want of that rest which a hospital would ensure them. One may fairly ask—If bad legs were as common, and productive of as much suffering among the rich as among the poor, how long would it be before a hospital was erected especially for them, and a number of anxious candidates appeared to contest the privilege of curing them? Without any wish to cast a slur upon the honourable intentions of the gentlemen who are supporters of an infirmary lately started, under great and affluent patronage, it might surely be asked, how it is, that with charitable motives only to guide them, an establishment is to be founded for crooked rather than for ulcerated legs?

Already all such cases are as freely received and as efficiently treated in the general hospitals as they could be in a special institution; and, therefore, an infirmary for their management is unnecessary and uncalled for, and in consideration of the evil of further separation of the pursuits of members of the profession, is unjustifiable.

We must say the same of all special institutions for the treatment of diseases of particular internal organs; all these are received into general hospitals, and

are regarded in them as objects of equal and just interest; neither is there required for their management any knowledge more than it is the bounden duty of every practitioner to possess. Why, then, should funds be abstracted from general hospitals to maintain others especially for the reception of patients affected with any one disease? If more hospital relief is requisite, let additional hospitals for diseases in general be founded, and let them all dispense alike the advantages of medical assistance, and of medical education; but let not the sums which the public are willing to give be frittered away in the treatment of one disease while another remains comparatively or entirely neglected. Surely there can be no more propriety in an infirmary for diseases of the lower bowel than in one for diseases of the mouth or the stomach; or in one for the affections of the lungs than for the affections of the heart; or for the disorders of the skin than for those of the muscles; for curvatures of the spine than fractures of the skull; for distorted than for broken legs. All that we know of these disorders is based upon the knowledge of medicine and surgery generally; they can, therefore, be rightly treated only by those acquainted with the general principles of these sciences, and in the education of the student instruction in them should form a part of one general scheme of study. Their separation from the main trunks of professional practice, even when (as in all the cases we have already alluded to) they are studied by men of general medical education, is not less mischievous to the advancement and propagation of medical knowledge than it is unnecessary for the well-being of those who suffer from these diseases, and unfair to those who suffer as much from others which receive only their average share of attention.

ROYAL SOCIETY.

Structure of Bone.

A PAPER was read, entitled "On the Structure of Normal and Adventitious Bone." By Alfred Snee, Esq., communicated by P. M. Roget, M.D. Sec. R.S.

On examining, by means of a microscope, very thin sections of bone, prepared in a peculiar manner, the author observed a number of small, irregularly-shaped, oblong corpuscles, arranged in circular layers round the canals of Havers, and also rows of similar bodies distributed around both the external and the internal margins of the bone. Each corpuscle is connected by numerous filaments, passing in all directions with the Haversian canals and the margin of the bone, and also with the adjacent corpuscles. He finds that the canals of Havers are vascular tubes containing blood. The corpuscles themselves are hollow, and their cavities occasionally communicate with those of the canals; their length is equal to about two or three diameters of the globules of the blood. They exist in cartilaginous as well as in osseous structures, and are found in every instance of adventitious bone, such as callus after fracture, morbid ossific growths either from bone or from other tissues; and the author has also ascertained their presence in the bony and cartilaginous structures of inferior animals, such as birds and fishes. Measurements relating to these corpuscles, by Mr. Bowerbank, are subjoined, from which it appears that their diameters vary from about the 10,000th to the 4000th, and their lengths from the 2300th to the 1400th part of an inch.

January 30, 1840.

On Single Vision.

A paper was read, entitled "Observations on Single Vision with two Eyes." By T. Wharton Jones, Esq. Communicated by Richard Owen, Esq., F.R.S.

The author animadverts on the doctrine which Mr. Wheatstone, in his paper on the Physiology of Binocular Vision, published in the Philosophical Transactions for 1838, p. 371, has advanced in opposition to the received theory of single vision being dependent on the images of objects falling on corresponding points of the two retinæ. He maintains that under these circumstances the two impressions are not perceived by the mind at the same instant of time, but sometimes the one and sometimes the other. If one impression be much stronger than the other, the former predominates over, or even excludes the

other; but still the appearance resulting from the predominating image is nevertheless in some manner influenced by that which is not perceived. He supposes that there are compartments of the two retinæ, having certain limits, of which any one point or papilla of the one corresponds with any one point of the other, so that impressions on them are not perceived separately; and considers that this hypothesis, combined with the principle above stated, is required, in order to explain the phenomena in question.

February 6, 1840.

Corpuscles of the Blood.

A paper was read, entitled "Observations on the Blood-corpuscles of certain species of the Genus Cervus." By George Gulliver, Esq. F.R.S. Assistant Surgeon to the Royal Regiment of Horse Guards.

The author has found that the blood of the Muntjac*, the Porcine†, and the Mexican Deer‡, contains, together with corpuscles of the ordinary circular form, a still larger number of particles of less regular shape; some curved and gibbous in the middle, and acutely pointed at the ends, with a concave and convex margin, like a crescent; others approaching more nearly to segments of a circle; some shaped like a comma, being obtuse at one end and terminated by a pointed curve at the other; others having an acute projection of the convex part, so as to constitute a triangular, or even quadrangular outline; some having the figure of the head of a lance; while a few presented a double or sigmoid flexure, as if they had been twisted half round at the middle. Like the ordinary blood-discs, these peculiar corpuscles are deprived of their colouring matter by water; but with only a small quantity of water they quickly swell out, and assume an oval or circular figure, forming long bead-like strings by the approximation of their edges. In saline solutions they become rather smaller, but preserve their figure tolerably well.

In an appendix, the author gives an account of his observations of the blood-corpuscles of a new species of Deer, inhabiting the mountains of Persia, of which a specimen has been lately received by the Zoological Society. Many of these corpuscles presented the singular forms above described.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY,

March 24, 1840.

SIR B. C. BRODIE, BART. IN THE CHAIR.

On the Structure of the Human Placenta and its connexion with the Uterus. By WILLIAM BLOXAM, M.R.C.S., Surgeon to Queen Adelaide's Lying in Hospital, and Lecturer on Midwifery at the School of Little Windmill Street.

THE author commenced this paper by a description of the appearances furnished by an examination of a uterus thirty hours after delivery. The uterus having been freed from its blood by gentle agitation under water, presented the following appearances. Its volume equalled that of the gravid uterus at four months; its internal surface exhibited the muscular fibres in rounded bundles, somewhat resembling those of the *carneæ columnæ* of the heart, except at the upper and back part on a circular portion, about six inches in diameter, where the placenta had evidently been attached.

At this part it was covered by a fine flocculent membrane, in which numerous openings of various sizes, with regular edges of an elliptic form, might be observed by turning it about carefully with the point of a fine needle. These openings led by regular channels to the surface of the uterus. Many of the openings were large enough to admit the little finger. At the bottom of these channels apertures of an elliptic, or sometimes of a semilunar, form were seen in the uterus, leading obliquely downwards into the sinuses of the organ. These openings were from two to four lines in diameter.

On looking through them, another class of orifices might be seen in the subjacent layer of muscular fibre; of the same shape, but less in size, also leading obliquely downwards into the sinuses of the uterus.

On laying open one of these large sinuses it was observed to be triangular in shape, the base being opposed to the outer wall of the uterus, and the veins of the uterus descending from the apertures above described, entered it at each posterior angle in pairs at intervals of from five to six lines asunder. These sinuses were continuous with the hypogastric vein, and were lined by a smooth membrane, apparently similar to that of the great veins of the trunk.

On examining the uterine surface of a recent placenta, it was stated that a considerable number of orifices of various sizes were to be shewn by inflation, and a cast of a placenta in white wax, with the edges of these orifices defined by black varnish,

was exhibited. They were found to vary in size and shape, some being circular but small, and the other larger and semilunar. The channels from these last-named orifices penetrated the organ obliquely, and extended into the interstitial structure of the placenta.

The obliquity of the canal rendered the semilunar fold of membrane, of which the orifice was formed, valvular in its appearance, and probably its function might be to resist the passage of blood from the uterus to the placenta in that direction. Indeed, from injections which had been made, the author had reason to believe that such was the fact; for a specimen was shewn, taken from a woman in the sixth month of pregnancy, in which the arteries of the uterus had been injected with red-coloured size, and the veins with blue. On opening the uterus, both systems of the organ were found to have been freely penetrated by the injection; that only, however, had reached the placenta which had been thrown into the uterine arteries.

In the same preparation were seen the vessels known by the name of the curling arteries of Hunter, making a sudden turn, and dipping at once into the substance of the placenta, at the spongy tissue of which they ramify minutely; so much so, that the surface appears of a uniform red colour, except when viewed under high magnifying power.

From these and other detailed observations, the following conclusions were deduced:—

1st. That the blood enters the placental system by means of the numerous slender arterial branches of the so-called curling arteries. That the number and minuteness of these arteries is peculiarly calculated to prevent the force of the circulation from being suddenly exerted on the placental system.

2nd. That the blood (or its nutritious principle) so introduced into the placenta is conveyed into these umbilical veins, which are in contact with the terminations of the uterine arteries, it may be either by secretion or by endosmose and exosmose.

3rd. That the blood having thus entered the body of the fœtus, is returned to the placenta by the umbilical arteries; by the free extremities of which either it, or some principle prejudicial to the child, is conveyed into the interstitial structure of the placenta, and thence, through the semilunar openings of the uterine surface, enters again the maternal circulation.

The author concludes by drawing attention to the mode adopted by nature for the prevention of uterine hæmorrhage, which is peculiarly provided against by the circumstance of no two of the elliptic openings in the inner surface of the uterus

being placed exactly on the same meridian; and also, that the flocculent membrane (decidua), which was described as attached to the part of the uterus from whence the placenta had separated, was well suited to entangle the blood in its tissue, and thereby to favour its coagulation.

Wound of the Throat.

A paper was then read by R. A. Stafford, Esq. Surgeon to the Marylebone Infirmary, detailing the symptoms and treatment of a maniac, a servant out of place, who had cut the larynx in full one half of its circumference with a razor; and who after the wound had been dressed by another surgeon, was brought by a policeman to the Marylebone Infirmary. The patient, in a recurrence of maniacal excitement, reopened the sutured wound, and enlarged it into the pharynx with a blunt knife. Food given passed out by the opening of the pharynx, and he was fed by a tube introduced into the œsophagus. The history begins on the 21st October, 1839, and the wound was completely healed on the 9th December following; but the voice of the patient was lost, and he could only speak in a whisper.

PATHOLOGICAL DEPARTMENT.

THE first meeting of this new branch of the Society was held on Tuesday, March 17, and was numerously attended.

The general purposes of this department will appear from the following memorandum, suspended in the library:—

BY ORDER OF THE COUNCIL.

1. General meetings of the Society shall be held on the third Tuesday evening in March, and the first and third Tuesday evenings in April, May, and June, 1840. These meetings are to commence at half-past 8, and not to extend beyond 10 o'clock.

2. At these meetings, members may bring under the notice of the Society, specimens recent or prepared, drawings or casts of morbid structures, accompanied by a description of the appearance, and a short history of the case.

3. Such members as are desirous of an authentic record of this statement being preserved must previously furnish the Secretary with a copy of it in writing; whereby the Council may also be enabled to decide on the printing of it in the Society's Transactions.

4. Specimens received shall be exhibited in the order in which they have been delivered at the Society's rooms; but precedence shall be given to those which previously to delivery have been announced to the Secretary. The order of such announcement shall regulate the order of precedence.

5. No recent specimens can be received at the apartments of the Society until half-past 7 o'clock in the evening of the day on which they are to be exhibited; and these recent specimens must be removed from the premises of the Society before 10 o'clock in the forenoon of the day following.

The Committee for regulating the proceedings of these meetings have resolved, "that at the meetings the oral method of description should be preferred."

HENRY LEE, *Secretary*.

March 16, 1840.

Owing to a mistake, we received no report of the first meeting, and the account we subjoin is taken from the *Lancet*, with a few corrections made for us by a member who was present.

Contused Artery.

Mr. Arnott showed a preparation and drawing exhibiting a peculiar condition of the humeral artery, consequent upon injury. A man was admitted, late at night, into the Middlesex Hospital, with five or six of his ribs broken, and a compound fracture of the left ulna, in consequence of the passage of a cart-wheel over him. The house surgeon did not deem the latter injury to be a serious one, and subsequently alleged that the pulse at the wrist was then perceptible. The following day (2d of October) Mr. Arnott saw the patient. The wound of his fore-arm was not considerable; the bone was not comminuted; the temperature of the hand was natural, but no pulsation could be detected in either the radial or the ulnar artery. The limb was attempted to be saved. The following day the temperature remained unaltered. On the 4th, the limb exhibited signs of mortification, being livid, mottled, and insensible: it was, accordingly taken off forthwith.

On examining the humeral artery, this was found about three inches below the seat of amputation, to be enlarged to a considerable size, and to be gorged with blood, which acted as an obstructing clot. The cellular coat was entire, while the inner and middle coats divided circularly, as if by a ligature, were, beyond this, separated from the cellular, and the two former still preserving their adhesion to each other, and their cylindrical form entire, were turned down and fairly inverted into the canal of the vessel further on; thus forming an additional cause of obstruction. Mr. Arnott had thought the case to be *unique*, but had recently learnt that one somewhat similar had occurred in the Birmingham Hospital, in a patient of Mr. Hodgson, who met with a compound fracture of the leg, and died, some weeks after,

of phlebitis. Soon after the accident, it was observed that there was no pulse at the left wrist, and, on examining the axillary artery after death, there was found in it an obstruction depending on the same causes as were observed in Mr. Arnott's case; the cellular coat being whole, the middle and inner coats divided, and these two adherent and inverted as a cylinder into the vessel beyond.

Mr. B. Phillips believed that two cases of a similar kind were recorded in the *Edinburgh Medical and Chirurgical Transactions*, by Mr. Turner. In one case, violence had been done to the arm, from which mortification ensued. The same condition of the artery as in Mr. Arnott's case, he (Mr. Phillips) believed was present. The other case was similar.

Mr. Arnott was acquainted with Mr. Turner's cases; in them the inner coats were torn irregularly, not simply divided, and inverted, as in his own case. An example of spontaneous gangrene—i. e. unconnected with external violence—had occurred in town, in which the same lacerated condition of the inner coats was observed as in Mr. Turner's cases.

Intestinal Concretion of Phosphate of Lime.

Dr. Bright exhibited an intestinal concretion or calculus, chiefly remarkable from its being composed simply of phosphate of lime, surrounding a nucleus of faeces. The patient from whom it was taken was under the care of Mr. Stone, and was six years of age. The symptoms presented were those usually observed in faecal abscess; there was a swelling on the right side of the abdomen, attended by gradual emaciation, and there was a discharge of pus and mucus, occasionally, from the bowels. In addition, however, to these symptoms, there was a discharge of puriform fluid from the bladder. The child died in twelve weeks after the first attendance of Mr. Stone. On examination, great suppuration was found at the caput coli, in which were two calculi; the one exhibited, which was about the size of a pigeon's egg, and another about half the size. From the composition of the calculi, it was at first suspected that they were formed in the kidney, and had escaped by ulceration through the right ureter; careful examination, however, proved this opinion to be erroneous. The calculi were formed of successive layers of phosphate of lime; the nucleus was a small portion of faeces. In another instance, under the care of the same practitioner, a number of calculi, of the same composition, had passed away from the rectum with the faeces.

Mr. Alcock remarked, that the phosphate of lime calculus was usually the re-

sult of chronic irritation of the mucous membrane of the bladder. Might not the intestinal irritation account for the formation of the bodies in the case under discussion?

Dr. Marshall Hall asserted, that calculi of phosphate of lime were never formed in the urinary apparatus: they were only formed in the prostate gland.

Mr. Erasmus Wilson had in his possession a portion of a colon in which there were a number of pouches containing calculi, probably composed of the phosphate of lime.

Disorganizing Inflammation of the Valves of the Heart occurring in connection with acute Rheumatism.

Dr. Watson exhibited some specimens of morbid anatomy, which were, as far as his knowledge went, perfectly unique in some particulars. They were cases of a peculiar kind of disorganization of the valves of the heart, resulting from acute inflammation connected with rheumatism. It was known well, that in articular rheumatism it was very common for some portions of the membranes of the heart to become inflamed; indeed, it had been calculated, that of cases of rheumatism of the joints occurring in London, at least one-third were complicated with some kind of cardiac inflammation, of which endocarditis and pericarditis were the most common. In the two cases from which the preparations exhibited were taken, the inflammation had fallen upon the lining membrane of the heart, producing a peculiar disorganization of the valves. In each instance there was a *ragged* perforation or destructive ulceration of one or more of the aortic valves. In both cases the muscular structure of the heart was diseased; in one instance there was ulceration completely through the septum, and in the other an abscess as large as a hazel-nut was found in the muscular structure of the septum.

The history of both cases was very similar. They occurred in young women of twenty-one and twenty-two years of age. Both were sufferers from a first attack of acute articular rheumatism; both had suffered from acute pleurisy, but had been free from pericarditis; one was ill three weeks, the other a month; both cases occurred in the same month; the sounds of the heart in both cases were altered, and there were palpitation and pain in that region.

The cases were peculiar from the rapid disorganization which had taken place from acute inflammation, from their connection with acute rheumatism, from the muscular structure being involved, perfora-

tion of the septum, and abscess of the substance of the heart.

Dr. Hodgkin said, that there were three or four preparations in a collection with which he had at one time something to do, similar to those brought forward by Dr. Watson. In one case there was perforation of the semilunar valves of the aorta, but he did not know whether the patient had suffered from acute rheumatism.

In one case of acute inflammation of the lining membrane of the heart, connected with rheumatism, a deposit was found on the edges of the valves without perforation. In another instance, which he had watched carefully during the last stage of the disease, and in which the physical signs resembled those which are present in retroversion of the aortic valves—the pulse remaining perfectly regular—a large aperture was found in one of the semilunar valves. There was also a preparation of a perforation of the mitral valve—he did not know its history. He had never seen pus in the muscular structure of the heart. In the few cases of acute carditis which had occurred, no suppuration took place before death, the patients perishing from other causes. He believed the deposits found on the edges of lacerated valves, or diseased portions of the lining membrane, were deposited from the blood, and were not exudations from the diseased structure.

Mr. Meade had examined a patient who had died with all the symptoms of acute pericarditis, but he did not know whether it was connected with rheumatism, in which the only lesion found was a large ulcerated hole through one of the aortic valves.

Disease of the Pons Varolii.

The case from which this preparation was taken was under the care of Mr. Henry Obré, assistant surgeon to the St. Mary-le-bone Infirmary. The patient was a boy nine years of age. About a week previous to his coming under the care of Mr. Obré, he had received a blow from a stone on the left malar bone. It produced no other inconvenience than ecchymosis. His health had always been good. About a week after the receipt of the injury, he showed an indisposition to play, and was attacked with diarrhoea, vomiting, and gradual loss of power in the left side. At this period he came under the care of Mr. Obré, when the following symptoms presented themselves:—As he lay, his head was thrown back, he complained of pain in the posterior part of it; there was violent strabismus of both eyes, which were drawn to the left angle; the pupil was obedient to light; the sight and motion of the lids natural; there was hemi-

plegia of the left side. He was sensible of the desire to pass his evacuations; the urine passed seldom, and in small quantities. A catheter was attempted to be passed into the bladder, but when it had been introduced about as far as the bulb of the urethra, its further passage was prevented by complete and violent priapism. The limbs, at the same time, were drawn up, and the whole body suffered from intense spasm. These phenomena were repeated at each attempt at introducing the catheter; but the moment the instrument was withdrawn, he returned to his former state of quiet. When the paralysed extremities were pinched, pain was felt; but he had no power of motion, except when the urethra was irritated: the motion was then involuntary. He had perfect sensibility and power of speech. He continued in this state for nine days, at the expiration of which he died. On examining the body the following day, the brain was the only organ which was found diseased; the dura-mater was more than naturally vascular and adherent to the bone; the brain was firm, and gorged with blood; on the under and right side of the pons Varolii, close to the pyramidal body, was a dark ragged opening, which communicated with a cavity in the pons, the size of a pigeon's egg, which presented the same appearance; there was also a smaller opening passing into the cavity from the left side; it contained no purulent secretion or fluid of any kind; the cavity occupied the right side chiefly; the pons was enlarged to double its natural size and weight.

Dr. Hodgkin had seen two cases of disease of the pons varolii; in one instance the disorganization was the result of apoplectic effusion; in the other instance, he did not know the cause of the disease. He thought that, although, in Mr. Obré's case, no fluid was found in the abscess, some had, probably, been there, and had escaped when the parts were removed.

Dr. George Burrowes exhibited a fine specimen of gangrene of the lung.

Mr. Stanley had a specimen of injured shoulder, and another of a rare form of hernia to show, but owing to the lateness of the hour these were deferred till next meeting.

ROYAL COLLEGE OF SURGEONS.

WE are not in general admirers of Sir Anthony Carlisle's lueubrations, and least of all of such as appear from time to time in the newspapers. The subjoined letter, however, really contains some strong facts, pithily given, and which certain parties would do well to bear in mind:—

To the Editor of the Times.

SIR,—I have "lived long and variously in the world" without meddling with affairs beyond those of my profession, and I ask the favour of a place in your paper for some medical observations which passing discussions seem to require.

The "men who turn the world upside down" are hotly pursuing the established institutions of English physicians, surgeons, and apothecaries, under the plea of "centralizing and equalizing," or of uniting the different classes of medical men.

If the agitators of these complicated projects had been themselves remarkably distinguished for professional talents and enlarged experience, the legislators, to whom they appeal, might equitably devote a moderate portion of parliamentary time, and of public money, to obtain impartial evidence, but the inquiry before a Committee of the House of Commons, in the year 1834, forbids any such hope.

That discontent has been fostered in every branch of the medical profession must be admitted, but after five years of unceasing agitation, out of 14,000 English surgeons the number of discontented does not amount to 600, a proof, at least, that the majority are not dissatisfied with their protecting college.

The British public, to whom these specious appeals against all established medical institutions are directed, should know how the reckoning between the rulers of the London College of Surgeons and its members have stood for the last 25 years.

The following is a statement of the expenditure:—

For the purchase and binding of books, and for the salaries of the officers of the library, to Midsummer 1839	£15,844
On account of the museum, including the salaries and wages of the officers and servants of that department, to Midsummer 1839	47,030
For the present building, including fixtures	41,803
Total..	£104,677

And whence came this £104,677? Not one shilling of it from the pockets of the members—not one shilling of it from the public taxes—but every shilling of it derived from the nightly labours of the Court of Examiners, appointed by charter to grant diplomas, the yearly accounts of which have been printed, for the satisfaction of all the members, in the annual lists.

And how stands the opinion of those members who send the candidates for Examination? The following table will show:

In 1837, were admitted for diplomas	303
1838,	588
1839,	675

Nor does any compulsory law or other obligation bring candidates to seek the diplomas of this College, for it is entirely optional, and the colleges of Edinburgh and Dublin are both open to English candidates upon less expensive terms.

This high station of the London College of Surgeons does not lead to any selfish incivilities, for its library and its museum are free to all men of research, and physicians, surgeons, and apothecaries, from all parts of the globe have daily access to those self-endowed depositories of medical knowledge. If the colleges of Edinburgh and of Dublin entertain a wish for equality, let them compete with the London Medical Institutions, and, if found to excel, they will assuredly obtain a preference; but, as universities for instruction, and also for the granting of licenses to practise, they have no analogy to the colleges of physicians and surgeons of London, which are not so constituted.

The preferable schools of surgical education in London, and of medical education at Oxford and Cambridge, have never ceased to produce surgeons and physicians celebrated throughout the world, and they will so continue to do, unless, through any unforeseen event, they should be reduced to a state of common mediocrity.

The London College of Surgeons has not importuned the Legislature with frequent or frivolous schemes for obtaining even needful powers, because the members of it well knew that the multiplication of laws has a tendency to create new sources of oppression, and that it is difficult to define the privileges of surgeons without interfering with the liberty of aiding the urgent necessities of human suffering; but, if the agitators for legislation must have an occasion for the interference of the legislature, the following declaratory enactment might serve to protect the public by proclaiming the names of legally qualified surgeons, and thus leave the adventurer and the quack to the judgment of the people. This enactment might be to the following effect:—

That those persons only who had obtained the requisite diploma, degree, or license to practise surgery, should assume the style or title of surgeons.

That those persons who should thereafter assume the style or title of surgeon without having obtained the requisite diploma, degree, or license, should be liable to certain penalties.—I am, sir,

Your very obedient servant,

ANTHONY CARLISLE.

Langham Place, March 24, 1840.

MORBID HYPERTROPHY OF THE MUSCULAR SYSTEM.

Two brothers born in the country had remained strong and healthy up to the age of 10 years; at that time they went to work in a very cold and damp village, and their health was soon affected. The muscles of their lower extremities increased remarkably in size; and the whole muscular system partook of the same affection, so that they were both disabled from their work, and were taken to the chief town adjacent, where they were received into the surgical clinique. Hip-baths were employed, but they seemed rather to aggravate their condition. The increase of size of their muscular system went on to an extraordinary degree. One of them died with symptoms of hypertrophy of the heart, (no examination was made after death,) and the other in the hospital of Incurables at Naples, under the care of Drs. Coste and Gioja, by whom his case is related.

He is now 18 years old, and in the following condition:—He is small, and from the absence of the signs of puberty, has the appearance of a child of 10 or 12 years old; the dimensions of his head are, however, in proportion to the size of his body, very remarkable; his tongue is at least one-third larger than in the natural condition; it fills the cavity of the mouth, and is an obstacle to him in chewing, speaking, and swallowing. The masticating muscles are very voluminous; the chest is short, the ribs are rather small; the abdomen, in consequence of the thickness and rigidity of its muscles, and especially from the extraordinary prominence of the recti, is large and hard. The muscles of the head and neck present nothing unusual. Among those of the back, one observes a considerable hypertrophy of the upper part of the trapezius, and of the digitations of the *lattissimus dorsi* and the *quadrati lumborum* are twice as large as in the natural state. But the most remarkable development is found in the upper and lower extremities. The deltoid muscles are three times as big as usual; and the *gastrocnemii* form an extraordinary prominence; the tendons of both are thin and hard. The other muscles are hypertrophied in nearly the same degree as the preceding. The bones of the limbs appear to be rather small, and as if they were atrophied, especially at the condyles of the femur and tibia. The forearm and the fingers are passively fixed in the position of flexion, and patient cannot extend either of them. The thighs are in like manner bent upon the pelvis, and the legs upon the thighs, so that the soles of the feet touch the ischia.

The feet are so bent that the back of each is in the same line with the outer ankle; and the sole is placed in the direction of the inner ankle. The skin covering the hypertrophied muscles is dark-red, and traversed by varicose veins. The functions of the genital organs appear to be scarcely developed; but those of the rest of the body are normally performed. The patient is employing iodine, both internally and externally, with some advantage.—*Schmidt's J. hrbucher.* xi 2. 176.

ADMINISTRATION OF QUININE BY THE SKIN.

A WRITER in the *Bulletin de Therapeutique* relates four cases in which intermittent fever was cured in children by rubbing into the axilla, an ointment composed of one drachm of sulphate of quinine with two drachms of lard.

HÆMORRHAGE FROM LEECH-BITES.

To the Editor of the Medical Gazette.

SIR,

YOUR last number contains a mention of the plan of stopping the bleeding from leech-bites with a needle and ligature. The following is, I dare say, nothing new, but I know to my comfort it is something useful. It is simply, instead of applying powdered argenti nitras, to use a stick of it scraped down to the size of the lead in a common drawing pencil. It may then be passed between the lips to the bottom of the wound, and being kept there a second or two it will—at least so I have found it—instantly and effectually stop the hæmorrhage.—I am, sir,

Your obedient servant,

JOHN BARRETT.

Bath, 17, Westgate Buildings,

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

BY BENJAMIN PHILLIPS, F.R.S.
Surgeon to the St. Marylebone Infirmary.

DISEASES OF ARTERIES—*continued.*

OSSIFICATION—DILATATION—CONTRACTION—OBLITERATION—ANEURISM—
Definition—Varieties—Spontaneous—State of Coats in—Most common Seat of—Causes—Dissecting Aneurism—State of Blood in the Sac—Changes in the Sac—Effects of Pressure in neighbouring Organs—Termination—Symptoms.

OSSIFICATION.

I HOLD that the depositions of which I have spoken, whether in the form of false membrane, of caseous, steatomatous, atheromatous, puriform, cartilaginous, or calcareous matter, have been a consequence of a low degree of inflammation; and that all, with the exception of false membrane, are most commonly seen in the cellular tissue between the internal and middle coats. I know that it is believed that they are not results of inflammation, because very commonly no vascular injection can be discovered at the point; but whether it be called inflammation, or whether it be termed a perverted nutrition, still I apprehend increased or deranged action has existed at the point. When osseous matter is deposited, it may occupy the middle tunic, and may consecutively implicate the internal tunic, or it may occupy the internal tunic alone. The former affects most commonly old people, in whom it was supposed, by Beclard, to be the last change which the fibrous tissue

undergoes; and is so commonly met with, that of ten persons above 60, Bichat states that we shall find at least seven presenting this condition. This condition is not always limited to points of an artery. Beclard states, that, at the Bicêtre, he saw, in an old person, the aorta and common iliaes converted into a true, solid, incompressible tube, and apparently composed of one solid mass. I saw a similar case at the St. Marylebone Infirmary lately, in a woman of the name of Sutherland, who died of senile gangrene. The arteries of the inferior present this condition, incomparably more frequently than those of the superior extremities: Lobstein states it to be in the proportion of 30 to 1. Indeed we may find, in very old persons, the femoral and its branches studded with osseous matter, while the brachial and its branches are completely exempt from it.

Lobstein gives the following as the order of frequency, and, as far as my opportunities of observation go, they confirm, in the main, his results:—

The arch of the aorta.
The bifurcation of the abdominal aorta.
Thoracic aorta.
Splenic artery.
Abdominal aorta.
Femoral and its branches.
Spermatic artery.
Hypogastric.
Coronary arteries of the heart.
Some branches of the subclavian.
Bifurcation of common carotid.
Inflexions of internal carotid.
Branches of external carotid; and last in frequency, the pulmonary artery.

Although these depositions are most commonly met with in aged persons, they may occur at other periods of life. Mr. Young had a temporal artery taken from a child of fifteen months, in which the membrane was converted into a calcareous tube. The aorta has been found ossified at three years. A complete ossification of the su-

perior mesenteric artery has been seen at 30 (Andral). However, as a general proposition, it may be laid down, that before 50 complete ossification is rarely observed. After that, this condition is frequently observed; but beyond sixty or seventy, the proportion does not seem to increase.

The analysis of this substance, made by Brande, shewed that it was composed of phosphate of lime, 65.5; animal matter, 34.5. Laissaigné's analysis is different—animal matter, 50; phosphate of lime, 47½; carbonate of lime, 2; sulphate of lime, some traces.

The second species of ossification is more frequently met with than the first, and almost exclusively occupies the internal tunic. It is seen under the form of yellowish plates, irregular, circular, elliptical, more or less thick and fragile. A thin pellicle at first separates them from the blood; but afterwards, either in consequence of the deposition of new matter or the destruction of the pellicle by erosion or absorption, it disappears, and they are directly in contact with the blood. The surface is usually smooth; but sometimes it is rough, and projecting into the canal. It is most frequently in the aorta, particularly in the arch, that this condition is observed, which co-exists commonly with a dilatation of the vessel and hypertrophy of the left ventricle. At the highest degree of this transformation, a third or a half of the circumference of this vessel is converted into scales of variable size, between which very small points, not ossified, may be found. Whether this condition be produced by a "drying up" of the nutritive arteries of the vessel, the deposition of an earthy or calcareous substance, by the friction to which the arterial tunics are subject, by the solidification of gelatinous fluids, by the "particular faculty which the internal tunic possesses of becoming incrustated with phosphate of lime," by inflammatory action, or by an ill regulated nutrition, it is extremely difficult to determine. So much seems certain, that it belongs to the senile age. Before that period of life it may show a precocious old age in the affected organ.

These depositions of calcareous matter may be the source of much mischief. The constant motion may direct their asperities against the internal tunic; it may become irritated and ruptured. The increase of deposit may produce a similar result. The blood introduced into these fissures, or into the cavities occasioned by the rupture of small abscesses, or steatomatous or atheromatous tumors—a sort of ecchymosis may be the consequence, and the cellular tunic may project, and thus the production of aneurism may result. Another effect may be the consequence; if the

parietes be thin, and the calcareous deposition considerable, the tunic may give way, and hæmorrhage be the consequence: in the cranium this occasionally occurs, and produces apoplexy. These concretions ordinarily lessen the cavity of an artery, and may completely obstruct it. There are cases recorded in which the calcareous matter has blocked up the vessel. There are others, of which Dr. Carswell has seen one or two, in which a projecting concretion has occasioned a coagulum and obliteration. They may cause arteritis, and a consequent coagulation and obliteration. It is said, that the absence of these concretions is a cause of longevity; and Thomas Parr is cited as a glorious instance of this fact. It is said, they are not found in long-lived animals, as the elephant, the eagle, &c. Another effect is attributed to ossification of arteries—gangrene. No doubt that the co-existence of ossification of arteries with gangrena senilis is very frequent; but if they stand to each other in the relation of cause and effect, why is not gangrena senilis more frequent? why is the disease now and then found without any calcareous deposition? I saw a case the other day of a young woman suffering under advanced tubercular phthisis, in whom the disease was presented at the tip of the nose, as well as at the extremities—in whom the extreme languor of the circulation could alone account for it. In gangrena senilis, if the calcareous deposition be a common cause, it must be by occasioning coagulation of the blood: gangrene, by the simple contraction of an ossified artery, can hardly, I should think, occur.

DILATATION.

As a consequence of certain of the changes or depositions which I have described, an artery may lose its elasticity, and a dilatation may be the consequence. The dilatation is commonly seen to affect more or less of the whole circumference of the vessel, and is usually observed in the aorta, in its whole length, the common carotids, and the subclavian. I show here probably an unique specimen of the same condition of the iliaes. This dilatation is sometimes accompanied by an elongation of the vessel; and it then presents a character not unlike that of a varicose vein. Sometimes there is no change in the thickness of the parietes; at other times they are thin and flaccid, like veins. So long as the internal membrane is not ulcerated, nor inflamed, the blood does not usually deposit clots in these pouches. Hereafter we shall have to point out certain exceptions. I apprehend the cause of this condition to be the impulsion of the blood, and consequent pressure against the parietes. In

the natural state there is a perfect equilibrium between the power of impulsion of the heart and the power of resistance of the arteries. If the force of impulsion is increased a third or a half, or is double, then, at each contraction of the left ventricle, the arteries are distended beyond their natural distensibility: this distension may be a cause of irritation and structural change in these parietes. We must admit that the resisting power has diminished at the point; otherwise we ought to find it much more frequently than we do at the arch of the aorta. The elongation of the artery during the systole of the ventricles of the heart is an admitted fact in the present day. To be convinced of this, we need only examine an artery at a point of bifurcation to see this effect; and it is, no doubt, by the constant repetition of this movement, that arteries are elongated by age, as is common in the descending aorta, the temporal arteries, and others. So long as the dilatation is inconsiderable, no inconvenience is experienced, but when the sac becomes large, its effect on adjacent parts is like that of the sac of an aneurism. The dilated portion of an artery may terminate in an ordinary aneurism. At some point, destruction of the internal and middle tunics takes place, in the course of the changes of structure by which the artery at first became dilated, and an aneurismal sac is developed. Recollect, however, that ordinarily, dilatation has not been the cause of aneurism, but the changes of structure by which the dilatation was preceded. May a simply dilated portion of an artery be converted into an aneurism? May it be filled with coagula? This is a question which we are now in a condition to resolve, and undoubtedly the opinion of Scarpa must undergo modification. We shall, however, reserve our evidence on the subject until we treat of aneurism.

CONTRACTION.

A diminution in the capacity of arteries has been principally observed in those of large size. Morgagni has seen the aorta reduced to the size of a little finger, in a man of 30. Desault has seen the thoracic aorta reduced to the size of a writing pen. Laennec has seen, in robust individuals, the diameter of the aorta not exceeding eight lines. Elliotson has seen the pulmonary artery twice contracted; in one case, so that the little finger could not be introduced into it; in the other, it was not larger than the humeral. Baillie has seen the femoral so constricted that light could not be seen through it. No doubt these conditions may be sometimes congenital, probably always so, in those where no change of structure can be detected;

but more frequently the diminution seems to be a consequence of the thickening of the parietes, from steatomatous, calcareous, or osseous depositions.

OBSTRUCTION.

These causes may proceed further, and produce obliteration; but obliteration is produced by many other causes: first, most transverse wounds, osseous spiculae, around which a coagulum may be formed, a rupture of the internal tunic, by the violent action of a limb, of which two cases are given by Professor Turner, in the Edinburgh Medico-Chirurgical Transactions; *arteritis*, which is no doubt the most frequent cause; by coagula consequent upon *sphacelus*, *gangrena senilis*, or other cause. The effects of obliteration are variable: if a coagulum occupy the whole length of the principal artery of a limb, gangrene is almost inevitable. When the obliteration is circumscribed, as after a wound or ligature, it is not so. When obliteration is caused by the rupture of the internal membrane, a sensation, as of something giving way, is experienced; the part is tumefied, the pulse on that side is either extinguished or much enfeebled, the member is cold, numbed, and its sensibility is diminished. Paralysis may be caused by the obliteration of the principal artery of a limb.

ANEURISM.

The term aneurism has been employed to describe several very distinct diseases of the arterial system; all being, however, accompanied by tumefaction or tumor. Thus the artery may be dilated without any destruction of its coats; this may constitute an aneurism. There may be a rupture of one or more of the tunics, the remaining tunics being more or less distended; this is also an aneurism. There may be a mechanical or other destruction of the whole of the parietes of an artery; blood may be poured out into the surrounding cellular tissue, which may or may not be condensed around; this is an aneurism. A wound or disease may establish a direct communication between an artery and a vein; this also is an aneurism. In fact, an aneurism may be defined to be a tumor formed by blood, sometimes contained within the dilated or destroyed coats of an artery, sometimes effused around an artery which still communicates with it, sometimes passing from an artery into a vein.

I do not propose to occupy you with all the distinctions insisted on—such as true, and false, and mixed, whether primitive or consecutive; because I believe them to be a source of confusion and unfruitful debate among the authors who employ them. I shall consider aneurism as spon-

tancons, traumatic, and varicose. Aneurism is a disease almost exclusively confined to the aortic system. I know of only doubtful cases in which the pulmonary artery was affected.

Spontaneous Aneurism.—Many conflicting opinions exist as to the condition of the arterial tunics in aneurism. Fernel maintained that every aneurismal tumor was a pure and simple dilatation of all the arterial tunics; others who supported this opinion, admitted that structural change could often be demonstrated in the internal and middle tunics. Sennert and Hildanus combated with success the theoretical ideas of Fernel, but greater development and consistency were given to their opinions by Scarpa. Scarpa did not deny that a dilatation of the tunics might occur, but he maintained that it was not aneurism. According to him, an aneurism is always the result of a pathological alteration, of a gradual destruction of the arterial parietes, which has permitted the blood to escape from the canal, and distend the cellular tunic of the artery. This celebrated surgeon has devoted much of his work to demonstrate this doctrine, which he has supported, not only upon the results of his own dissections, but upon a profound examination of the observations published by his predecessors and contemporaries; and we cannot deny that Scarpa has rectified the ideas of those who went before him upon this subject.

Scarpa, and other eminent surgeons, do not consider a dilatation to be an aneurism, whether it occupy the whole circumference of an artery or only a part of it; and the distinctions which he lays down between dilatation and aneurism are intended to support this position. According to him, dilatation differs from aneurism, because it commonly occupies the whole of the circumference of the vessel, while aneurism is limited to one of its sides. Aneurism communicates with the artery by a kind of neck; whilst, in dilatation, no such contracted communication is found. In the interior of aneurismal tumors, clots or fibrinous concretions are found; these are not found in simple dilatation. In aneurisms, the membranes are often disorganized or destroyed; in dilatations they remain healthy, or only present inconsiderable changes of structure. Here, then, we have the alleged differences fairly set out, as well as the reasons why dilatation should be held to be a disease distinct from aneurism. Mr. Hodgson differs widely from Scarpa: he admits, that, at an early period of its existence, an aneurism may consist of simple dilatation; but he does not admit that they are seen, except very rarely, when the

tumor has acquired a certain bulk. Now I shall adduce the evidence which may be fairly urged for the purpose of shewing that such opinions are too exclusive. If it had merely been stated that the term aneurism was limited to a particular form of disease, characterized by a destruction of the internal and middle tunics, I should have no right to find fault with the limitation; but as the reasons are distinctly given why dilatation should be excluded, it is not unbecoming in me to endeavour to shew that the objections are inconclusive. In the first place, there are carefully recorded eleven or twelve cases observed by Baillie, Zannini, Corvisart, Berard, Cruveilhier, Dance, Breschet, and Thurnam, of pure and simple dilatation of a portion of one of the ventricles of the heart. There was demonstrated, in several of them, a perfect continuity of the tunics; there was a contracted point of communication, or neck, between the cavity of the tumor and the cavity of the ventricle; and in all, I believe, coagula were found. A considerable number of cases, observed with the greatest care, are also before us, where the same condition was demonstrated in the aorta; the dilatation was partial, occupying one side of the vessel, the tunics were perfectly continuous, but ossific matter was deposited in them. The fundus of the tumor was considerably larger than the point where it communicated with the artery, and they contained coagula, which, in several cases, were ranged in regular layers. Where the dilatation affects the whole circumference, coagula do not seem to be usually deposited. Similar tumors, dependent upon pure and simple dilatation, have been observed in the common carotid, external and internal iliacs, middle meningeal, temporal, subclavian, axillary, brachial, coeliac, and splenic trunks, the smaller cerebral, the femoral, and the ulnar arteries. At present, we believe these cases to be rare; and, no doubt, when they have acquired a certain volume, the internal and middle tunics are ruptured, the external tunic alone remaining to resist the impulse of the blood; and at this time the tumor offers the exact conditions of one which was the consequence, from its commencement, of the perforation of those tunics.

The position assumed by some persons who have felt themselves bound to admit this condition of the aorta, that this is a condition peculiar to the aorta, is therefore untenable; and I have no doubt, now that the disposition is set on foot to investigate carefully this point, we shall annually have fresh evidence in support of the necessity of modifying the opinion of Scarpa and Hodgson, but our gratitude to these men

should not be less, because we find it necessary to advocate a certain modification of their definition. At present our facts do not enable us to go further than to state, that occasionally aneurismal tumors are constituted by a simple dilatation of the arterial tunics. At the same time my firm opinion is, that when aneurism is spontaneously produced, commonly it is primitively formed by a dilatation of the three arterial tunics, of which the internal and middle are more or less changed in their structure. At a later period, under distension these tunics give way, and then the condition described by Scarpa and Hodgson exists: supposing this opinion to be correct, we should return to the definition which in the present century has been generally discarded, that a *true aneurism* was a tumor formed by the *dilatation of the whole of the arterial tunics* at a point of the circumference of the vessel; that a *false aneurism* was a tumor consequent upon or resulting from the rupture of the *internal and middle tunics*, and the extravasation of blood, arrested only by the resistance of the external or cellular tunic. Such are the modes by which aneurisms are spontaneously produced; but they may succeed to wounds or other direct injuries, and they are then termed *traumatic aneurism*.

Aneurism spontaneously produced is most frequently observed to affect the large arteries in the vicinity of the heart—the external iliac, the femoral, the popliteal, the subclavian, and the axillary. The arteries of the arm, the forearm, the hand, the leg, and the foot, may also be affected; those of the interior and exterior of the cranium are also occasionally affected; and in the museum of M. Schmiedler, at Fribourg, is a preparation which shews a similar condition of both the central arteries of the retina.

Although commonly we find only one aneurismal tumor in the same individual, yet occasionally we may see several. Pelletan saw on a single individual, 63 aneurisms, varying from the size of a filbert to that of a hen's egg. Sometimes, as in a case described by Sir E. Home, no sooner is the operation performed for the cure of one, than another is manifested in the other extremity. When this predisposition seems to exist, slight causes may occasion their development. Mott speaks of a man who, in making a violent effort to raise a load, saw arise an aneurism of the left femoral: some time after, the same person, by stamping violently, produced a popliteal tumor. Gosshalk relates a case where there was an aneurism of the right popliteal, two of the left femoral, a fourth, large, of the abdominal aorta, a fifth at the arch of the same vessel.

Causes.—These tumors are unquestion-

ably much more rarely seen in women than in men; although they suffer as often as men from many of the diseases to which the development of aneurism is ascribed. This immunity may be a consequence of greater sobriety, less violent efforts and laborious occupations: but it is in the popliteal artery that this difference between the sexes is most marked. Mr. Guthrie holds the proportion to be twenty or thirty to one. I have collected ninety-two cases, of which three occurred in women. Wilson says, he heard John Hunter say, that he had never seen a case of spontaneous external aneurism in a woman. Hodgson collected 63 cases, of which 56 were men and seven women, or about eight to one. I have collected 163 cases, of which 142 were men and 14 women, or about eleven to one. Mr. Guthrie believes that its frequency in man depends on the greater use he makes of his legs. Richerand says, that of twelve cases of popliteal aneurism he had seen, ten were probably produced by violent extension of the leg. If, says he, you place a leg on the table, and make sudden and violent extension, so as to produce a crackling sound, and then carefully examine the artery, the middle tunic will be found to have given way. In this experiment I have often failed, and only very rarely succeeded. With respect to the opinion which refers the development of aneurism to the employment of mercurials in the cure of syphilis, if it were a real cause, it ought to operate more frequently on women, for they are as subject as men to syphilis and the remedy. Until after puberty, a diseased condition of the arterial tunics is comparatively rare; aneurism is equally so.

I have made a calculation for the purpose of estimating the comparative frequency in each artery: the cases collected amount to 195, of which 61 were popliteal, 46 femoral, 18 carotid, 19 subclavian, 14 axillary, 8 external iliac, 5 innominate, 4 humeral, 4 common iliac, 3 anterior tibial, 2 gluteal, 2 internal iliac, 3 temporal, 1 internal carotid, 1 ulnar, 1 peroneal, 2 radial, 1 palmar.

As to age, I have got together 122 cases, as follow: under 13 years, one; from 15 to 20, three cases; from 20 to 25, five cases; from 25 to 30, twelve cases; from 30 to 35, twenty-four cases; from 35 to 40, fifteen cases; from 40 to 45, twenty cases; from 45 to 50, seventeen cases; from 50 to 55, eleven cases; from 55 to 60, seven cases; from 60 to 70, four cases; from 70 to 80, three cases. One thing is shewn as to age, that aneurism is very much more common between 30 and 50 than in the ten years before and after; and that before 20 and after 60 the disease is very rare.

It is extremely difficult, if not impossible,

to point out with any certainty the causes of aneurism. I believe an aneurismal tumor is almost always preceded by a structural change in the parietes of the vessel; that change would, therefore, constitute a secondary or predisposing cause; and our inquiry must therefore be directed to the conditions under which these changes are most commonly developed. Among the causes which are supposed to conduce to the change of structure in arteries, are hypertrophy of the left ventricle, bifurcations or curvatures of the arteries, against which the blood is propelled almost perpendicularly—contiguity of the heart—unfavourable conditions of large arteries—their parietes being disproportioned to the capacity of the canal position; in the vicinity of articulations, by which they are subjected to extensive movement; immoderate indulgence in wine, excessive venery, mercurials long administered, and syphilitic infection, which according to Morgagni, Corvisart, and Scarpa, exercises an action which occasions softening, renders them friable, or produces ulceration, herpetic affections, scrofula, scorbutus, rheumatism, and gout. These changes in structure are a deposition of ossific, atheromatous, steatomatous, or purulent matter, which causes ultimately a solution of continuity in the internal tunic. That the cause is a general one seems probable, from the occasional universality of the disease. Lobstein gives plausible reasons why it should be referred to a disposition similar to, or identical with arthritis; he believed that this morbid principle acted upon the arteries as upon the bones: he details a certain number of cases, in which arthritis, or the disposition to it, seems to be exciting cause of similar depositions in the arterial tissues.

In this state I am obliged to leave the question, feeling that I am not in a condition to recommend either for your adoption, though I incline to the opinion that chronic inflammation is the more probable; nor denying that one or more of these influences may concur to produce that change in the arterial tunics which I have already set forth, and which predisposes to the production of aneurism. Now these dispositions having occurred, the internal tunic loses its smoothness, becomes unequal and rugous; by little and little yellowish patches appear, together with calcareous laminae, the internal tunic becomes friable, is separated from the middle tunic; if pressed with a finger or cut with a scalpel a crepitation like that resulting from the pressure of a piece of egg-shell is heard: as the disease advances, an ulceration is seen, the internal and middle tunics give way, the former as much more easily, as, in consequence of its natural fragility, it

opposes less resistance to the impulsion of the blood. At the circumference of the opening so produced the internal tunic may be seen usually terminating abruptly, and the middle tunic commonly cannot be followed around the sac, which is formed of the distended and dilated external tunic.

The experiments made by Nicholls, before the Royal Society, and repeated by many others, explain very well how, as a consequence of the ulceration of the internal and middle tunics, the blood, influenced by a lateral movement, raises or distends by little and little the cellular tunic, and forms a tumor. If, when those two membranes are destroyed, we inject water, or air, we see the external tunic raised in the form of a globular tumor. Thus, then, in the case of a solution of continuity of these tunics, the cellular coat sustains the lateral impulse of the blood; and when this resistance is vanquished, the sac is extended, and the blood accumulates in great quantity; but, happily, this blood usually becomes concrete and organized, constituting an obstacle to the rupture of the sac, and life is not, consequently, immediately compromised.

In a few cases, instead of raising the cellular tunic in the form of a more or less globular tumor, the blood passes down for some distance between the external and middle tunic, ultimately forming an extensive lateral or circular sac. Laennec observed it in the aorta, and termed it "*aneurisme dissequante*." Mr. Guthrie has seen such a sac on the aorta six inches long; with that vessel it communicated by a transverse fissure an inch in length: he has since seen a second case, in an old woman who died suddenly from a perforation of the innominate: the "dissecting aneurism occupied the ascending portion, the arch, and two inches of the descending aorta." Shekelton saw two fine specimens of this disease: the blood had formed between the external and middle tunics a sort of collateral canal, recommunicating afterwards with the vessel, receiving above a column of blood, which below, it again restored to the vessel: a false membrane invested this canal. There are also similar cases by Morgagni (Ep. 58, No. 13,) Nicholls, and McLacklin. In the 45th number of the American Journal of the Medical Sciences is a case of the same kind. The patient, a woman of 75, had dyspnoea, with forcible impulse of the heart; rhythm nearly natural. Upon examination, the heart was found of double its natural size. The aorta was apparently much dilated, and, when cut into, presented the remarkable appearance of being a double vessel, (see fig. 1.) The aorta was nearly surrounded by another vessel of much larger diameter, commenc-

ing opposite the great sinus of Valsalva, which accompanied the aorta until it divided into the primitive iliacs, where it

terminated in a cul de sac. The aorta communicated with the external vessel by a valvular fissure half an inch in length, which penetrated through the internal and partly through the middle coat, and which is situated half an inch above the semilunar valves. Not long since a very fine specimen of this disease was observed at the St. Marylebone Infirmary. The patient, a man of sixty, had a large heart, and chronic bronchitis: he died suddenly. Upon examination after death, a stellated laceration of the internal and middle tunics of the aorta was observed just above the semilunar valves. Through this point the blood had passed, and had separated the internal and middle tunics for the distance of a foot, extending along the thoracic aorta. The coagulum was about as large as an ordinary sized thumb.

When a violent effort or contusion is the accidental cause of the development of an aneurism, they usually occasion rupture of the diseased tunics, the blood is no longer sustained by any other than the external tunic, and the aneurism may appear suddenly, and in a short time acquire considerable size. At the time, the patient very often experiences an acute pain, and the sensation of something giving way; a numbness is felt at the parts beyond the rupture, which now and then cannot be moved without difficulty. Among these some might with propriety be classed as traumatic, for at the point there is a fair rupture, without dilatation or structural change; but as the external tunic is not destroyed in these, and as the whole are destroyed in traumatic aneurism, we shall prefer considering them in this place.

Under ordinary circumstances, the destruction of the internal tunic is of very small extent, the blood escapes in very small quantity, and at first it is a mere ecchymosis between the fibrous and cellular tunics. The extravasated blood is coagulated, and, in the first instance, blocks up

the opening, the part is distended by the lateral impulse of the blood, more blood escapes, and fresh coagula are formed. After some time the opening becomes of sufficient size to admit of the flux and reflux of blood. It may then be observed externally, and its progress is more rapid. When an aneurismal tumor is at first a consequence of simple dilatation, its progress for some time is very slow. After remaining apparently stationary, a sudden increase in size is observed; this increase may follow immediately upon great exertion, violent movement, a fall, a fit of coughing, or of passion. When it succeeds to any of these, the internal and middle tunics have given way; the external, more extensible, is dilated by the blood poured into it, and the tumor is the consequence: these tunics may give way without such exertions; but the increase is then usually less rapid.

Corvisart pointed out another mode by which aneurism may be spontaneously formed: he shewed that the destruction of the middle and internal tunics may be from without—by the development of “encysted tubercles under the external coat; by this means the aneurismal sac will precede the aneurism.” This opinion of Corvisart was almost lost sight of when Mr. Hodgson considered the matter further. The conclusion to which he came was, that those bodies were not tubercles, but a condensation of fibrous laminæ which had constituted aneurismal sacs no longer existing. Mr. Guthrie pointed out that Hentzel, in 1793, had stated that the matter contained in these tumors was very different from fibrine, and that a similar steatomatous matter was contained in the cases of Corvisart. Similar cysts have been shewn by Berard and others. Probably the tumors seen by Hodgson were cured aneurisms, those of Hentzel, Corvisart, Guthrie, and others, were cysts developed under the external tunic of the aorta: these cysts might open into the aorta, and become aneurismal sacs, as is testified by the fact contained in the *Compte Rendu of the Anatomical Society for 1829*. I doubt much whether they are often so observed, or elsewhere than in the aorta.

State of the blood in the sacs.—The blood contained in an aneurismal sac has occupied much attention: it is deposited in layers, which have occasionally traces of organization, so marked that Valsalva took them, on two occasions, for “carniform excrecences of the arterial parietes.” It is particularly in circumscribed aneurisms that we meet with this coagulum—more rarely in those which are diffuse, at least unless they be of long standing. These masses present a varied aspect ac-

cording to the length of time since their deposition, and, according to Laennec, to other circumstances which it is not easy to appreciate. The more central are formed of recently coagulated blood, external to these the coagula are firmer, and of a blackish red colour, and evidently pervaded by a certain quantity of fibrine; more external still, layers of pure fibrine, white, or yellowish, firmer, and less humid than the polypiform concretions of the heart. These masses commonly offer an assemblage of concentric layers; the external of which are brownish, dense, and coriaceous, becoming, as we approach the centre, paler and softer. For a certain time these clots contribute to sustain the parietes; but, in accumulating, they ultimately contribute to accelerate the rupture of the sac by causing ulceration of its walls.

It is singular how rapidly clots are deposited in the smallest aneurismal sac, if the internal tunics be destroyed, whilst they are often wanting in the largest dilatations when the tunics are entire. Certainly the diminished movement of the blood is not the only cause of the coagulation; and we are constrained to admit, that the membrane with which it is in contact exercises some influence on this phenomenon. Coagulation of the blood is one of the most constant consequences of inflammatory action in the arterial parietes. The cellular coat, irritated by a fluid which is new to it, becomes the seat of a low degree of inflammation, but enough, however, to produce coagulation of the blood which is in contact with it. A proof of this is furnished by the lymph which is found on the surface of the sac; but, although this matter is often secreted, I know of no positive case of complete adhesion of the coagulum to the sac. Destruction of the internal tunic is not, however, absolutely necessary to ensure the deposition of coagulum in a sac; the low inflammatory action excited by the deposits, of which I have already spoken, is sufficient for this purpose.

Changes in the sac.—As the sac increases in size, its parietes increase in thickness, at least for some time; in some cases becoming very thick, fibrous, or even cartilaginous. Some aneurismal sacs experience a thinning at several points; the tumor may extend irregularly in the several directions where the thinning occurs, and the appearance of secondary sacs is presented. The adhesion of this sac to surrounding parts is more or less intimate. A sac may be very small, and may rupture before adhesion is advanced enough to resist the impulse of the blood which escapes into the adjoining tissues. Hodgson gives the case of an old man, who, whilst walking, felt a sudden pain in the

middle of the right thigh; he looked at the part, and perceived a small swelling. The pain increased, the tumor enlarged, and, in a few hours, the whole limb was cedematous. The tumor was compressible, but it was only a few hours before death that any vibratory pulsation could be distinguished. The man became very feeble, the tumor enlarged, and, in three weeks from its first appearance, he died. The muscles of the thigh, separated from each other to a vast extent, were filled with coagulated blood; which, in the triceps, hollowed out a large cavity. The artery communicated with this sac by a small round opening, not larger than the ordinary calibre of the vessel. This opening was evidently that of a small aneurismal sac, which had suddenly given way, and had given rise to extensive extravasation. The original sac was not larger than a pea, and was formed by a partial dilatation of the arterial tunics, which were thickened, and encrusted with calcareous matter.

Certain changes happen in the neck of the sac: commonly, the opening is irregular, the edges jagged and floating, and it is usually situated at the centre of a kind of septum, formed by the perforated internal and middle tunics. These membranes very commonly terminate at the neck of the sac, presenting a kind of rim or collar; sometimes, however, the membrane of the cyst is continuous with the internal tunic. This opening does not, however, always correspond to the centre of the aneurismal tumor, which has found less difficulty in dilating towards one point than another. In the extremities, this opening is often found nearer the superior than the inferior part of the tumor. If the ulceration extend, this septum may disappear; and the neck is then more or less completely wanting. In Guattani are found two figures which perfectly express this condition: the artery seems to open into the superior part of the sac, and to emerge from the inferior portion. It was just this disposition of sac which induced Sir Astley Cooper to recur to the ligature of the aorta for an aneurism of the external iliac.

Effects of pressure of sac on neighbouring organs.—If a circumscribed aneurism do not increase or interfere with the functions of neighbouring organs, it may be borne long with impunity; but if it go on enlarging, no organs seem to be capable of resisting its destructive influence. At first these organs are pushed aside; but, as the tumor makes progress, it adheres to them, and then they begin to suffer. Muscles, tendons, nerves, and other tissues, are disorganised; the bones, spite of their solidity, constantly acted upon by the pulsation of the tumor, are ultimately hollowed out, the periosteum disappears, and, at

last, under the influence of the pressure they experience, are absorbed and destroyed. It is not caries or necrosis under which the absorption is determined; no debris are seen, and no alteration of the remaining part is apparent. The articular and fibro-cartilages resist this influence longer than any other organs, but they at last give way. This circumstance explains the symptoms which are often accidentally developed in the course of its progress. Nerves disorganised or destroyed, explain the pain, the numbness, the cramps, occasionally felt. As to the arteries, the tumor exercises considerable influence upon them; by the compression it occasions, the arterial canal is lessened, and the superior branches are dilated to supply parts beyond the tumor. This is a very important circumstance, which prepares for the success of an operation. All operations of this kind succeed best in cases in which old aneurismal tumors have in that way prepared the collateral circulation; and, indeed, it caused the adoption of the principle, that it is wise to delay the operation until the tumor has acquired a certain bulk, and prepared the collateral circulation for the event. Still the principle must not be pushed too far.

Termination.—If art do not interfere, the tumor, by destroying one organ, and pushing aside another, approaches either the surface, or one of the great cavities; it increases in size, and ultimately bursts. How this result is effected it is not easy to say; the layers of coagulated matter, by which the sac is filled, are successively formed, and are as much more coherent as they are older, the colouring and fluid portions having been absorbed. Are these concretions organized? Their regular disposition in concentric layers, their tenacity, their adhesion to the arterial parietes, are circumstances which have served to give an affirmative answer to the question. I do not deny the possibility of it, but I have never seen it demonstrated. The regularity of the concretion is no proof of vitality; it is analogous to crystallization. These concretions are a barrier which is efficiently opposed to the rupture of the sac; they seem to increase in proportion to the danger of rupture. But sometimes the impulse of blood overcomes the resistance, and then it finds a way through the concretions, gets between them and the walls of the sac, which it irritates, and rupture follows. Most frequently, however, the morbid action which takes place in the parietes ends in the secretion of pus, which is infiltrated through the contents of the sac, and produces a fluctuation where before all seemed unyielding. This fluctuation in a case of aneurism of the aorta, not many years ago, induced in the mind of a practi-

tioner an idea of abscess; it was punctured, pus flowed, then a few drops of blood, and in a few days the patient died, though not from hæmorrhage. The moment of perforation in such a case is often that of death, unless the opening be very small. Sometimes the opening is a mere crack, and only very small quantities of blood escape, and then life may be extended days or weeks.

Symptoms.—A true external aneurism is presented under the form of a tumor, usually indolent, circumscribed, and rounded, compressible and elastic, whose progress is usually slow, until the internal and middle tunics give way. This tumor, situated in the course of an artery, is accompanied by pulsations isochronous with those of the arteries; it may be lessened or even disappear under compression, or even when pressure is made upon the artery above it; on the contrary, it enlarges, and its pulsations are stronger, when the artery is compressed beyond the tumor; it does not interfere much with the motion of the part, and the colour and temperature of the part are not changed. Having remained for some time in this condition, it undergoes certain changes; under some effort, or even without, the tumor enlarges rapidly, the patient sometimes experiencing a sensation as if something gave way, the tumor becomes firm, unequal, and pressure no longer causes it to disappear; the pulsation in it becomes more obscure, being often reduced to a mere thrilling sensation. Any pulsation which may exist, at once disappears if the artery above be compressed, but at that time the bulk of the tumor remains unchanged; the skin over it may be distended, thinned, sometimes inflamed, or even surrounded by a gangrenous spot; pain may be felt in the tumor, or in the limb beyond it, the subcutaneous veins are sometimes varicose, the limb more or less œdematous, benumbed, and even cold.

Symptoms so numerous and so characteristic would appear to be sufficient in all cases to prevent mistake, yet unfortunately how often have aneurismal tumors been mistaken for abscess, and opened by an incision which has quickly caused the death of the patient! It is an error which can scarcely happen when the tumor is small, because the pulsation of the tumor, and its disappearance under pressure, are so characteristic, that we cannot doubt of its nature. But when the disease is advanced, the tumor large, filled with clots, pulsations indistinct or absent, and compression bringing no change in its bulk, difficulty in diagnosis is much increased. In such a case, the examination must be very carefully made; the earlier history must be minutely considered before a decided opinion is expressed; if we learn

that at first it was very small, that it has gradually increased, and that afterwards, after some effort, or without any apparent cause, it has suddenly increased; if at its commencement it has presented pulsations, which have gradually lessened, and at last entirely ceased—if compression, which at first caused it to diminish or to disappear, no longer produces in it any sensible change—we may say with certainty that the tumor is an aneurism. But in the greater number of cases, the earlier history of the disease is unsatisfactory; the difficulty is even increased by the absence of the characters of aneurism, the presence of those of abscess, and the tumor is opened: this has, many times, unfortunately happened. An aneurism has many times been mistaken for an abscess; so tumours of various kinds, situated in the course of large arteries, have been confounded with aneurism. Still the history of the disease, and the beating of the tumor, may furnish sufficient information to detect the disease. Aneurism, at its commencement, is a soft tumor which disappears under compression, most other tumors are as much firmer as they are less advanced, and do not disappear under pressure. As an aneurism advances, it loses its softness, as it increases in bulk, and this change in its consistence always extends from the circumference to its centre, so that this point is still soft when the base has become hard. In abscesses which soften with the progress of suppuration, fluctuation is always found at the centre, and extends to the circumference. In aneurism, the beating is manifest, whatever be the attitude of the limb, in other tumors, which are moved by the pulsation of the artery, this symptom ceases to be sensible when such an attitude is given as will change the relation of the vessel with the tumor. The beating in aneurism is as much more marked as the tumor is small, and the coagula in the sac few; the beating in tumors of other kinds is as much stronger and extensive as the tumor is larger, because they press more heavily upon neighbouring vessels, and increase the lateral effort of the blood. The beating in aneurism is a true expansion or dilatation, sensible over the whole circumference when the tumor is not large, nor of long standing; sensible only at its centre, and obscure or absent at the base, when the sac is large and filled with coagula, whilst the beating of other tumors is a simple displacement of the whole mass, sensible in its whole extent, and, as it were, perpendicular to the axis of the vessel by which it is communicated. From all this it results, that in many cases it is impossible to give an opinion whether a tumor placed in the course of a large artery be an aneurism or

some other tumor. In these doubtful cases, it were best to treat the case as if the tumor were aneurismal. Following this rule, it may undoubtedly happen that we shall refrain from meddling with some tumors which should be opened, but the inconvenience of this plan of proceeding cannot be compared with the danger to which a patient is exposed when an aneurism is opened for an abscess. It is particularly in the treatment of tumors of the trunk, the neck, the axilla, or the groin, that this prudence and circumspection are especially necessary; in those of the extremities, we may restrain the hemorrhage by compressing the artery above the tumor; but even then, before opening a suspicious tumor, all things necessary for the ligature should be at hand.

GUY'S HOSPITAL.

From the Report of the Commissioners for inquiring concerning Charities.

JOINT REPORT OF MR. SMITH AND
MR. MARTIN, DATED JUNE 1837.

THOMAS GUY, Esq. of the city of London, having obtained from the governors of the Hospital of St. Thomas, in Southwark, a lease of a parcel of land for 1000 years, commenced the erection thereon of a building intended for an hospital. By his will, bearing date 4th September, 1724, after various bequests to several persons, and after giving an annuity of £400 a-year to Christ's Hospital, that his executors, or the incorporated trustees of his property, might have perpetual right to nominate four children yearly to be received and educated there, and after leaving sums for the support of alms-houses at Tamworth, (Stafford), and for many other charitable purposes, he proceeds to the bequeathing of the property by which this Hospital, which bears his name, was completed, and has been since in part maintained.

After the payment of all the bequests mentioned in the previous part of the will, he gave all the rest of his property to Sir G. Page, Bart.; C. Joy, Esq. treasurer; and W. Clayton, T. Hollis, J. Kenrick, J. Lade, Esqrs. governors of the then Hospital of St. Thomas; and to Dr. Richard Mead, M. Raper, Esq. and John Spruit, likewise governors of the said Hospital, and their heirs, &c. upon trust, for the purposes afterwards directed. These trustees, till an Act of Parliament could be obtained to incorporate them, and certain others mentioned, were, from the property which he left, to finish and fit up the two new squares of building in Southwark which he had some time since begun, and intended for an hos-

pital; and to build such other offices as they deemed necessary, and furnish the same with all conveniences, for 400, or more, sick and poor persons, who might be thought capable of relief by physic or surgery. They were authorised, however, to receive a number of patients, not exceeding 20, lunatics, or any others who, being deemed incurable, could not be admitted into St. Thomas's Hospital, or others similarly constituted; and these 20 were to be chosen, by the trustees, from among the patients dismissed as incurable from St. Thomas's, or, after them, from any poor persons who might apply. The patients received into the Hospital were to be provided with food, physic, and all other necessaries during the remainder of their lives, or as long as the trustees might deem fit; and, in short, all the arrangements, except those for incurable patients, were to be made as near as might be according to the customs and usage that, of late years, had prevailed in St. Thomas's Hospital.

For the more secure and permanent management of the Hospital, he earnestly requested that his executors and trustees would forthwith, after his decease, endeavour to obtain letters-patent, or an act of Parliament, incorporating them, and all who were alive and willing to act of 51 others, governors of St. Thomas's, whom he particularly named, and as many others as they might deem necessary, to make up a body of 50 at least, and not exceeding 60, to form a distinct and separate body politic and corporate, with perpetual succession, for the government of the Hospital. He desired that, by the letters-patent, a president and treasurer, and such other officers as might be deemed necessary, should be named and appointed, to be successively elected and admitted, and have perpetual succession; and that, by the same letters-patent, a committee of 21 members of the incorporated body should be named, and have granted to them such powers as might enable them, in the most efficient way, to settle and apply the property devised to the Hospital. Seven of this committee were to go out, and seven to be elected annually; their management and accounts to be submitted to a general court of the whole body of governors or members of the intended corporation. It was also desired, that in the same letters, if they could be obtained, it should be provided, that the future elections of the president and treasurer, and also of the physicians and surgeons, and of the clerk, solicitor, and chaplain, should be reserved to the general court of governors; and that the offices of apothecary, steward, matron, cook, sisters, and all other officers, should

be elected by the committee (of 21). As soon as the act of incorporation could be obtained, the trustees appointed in the will were to transfer all the property to the incorporated governors, upon the same trusts as they had themselves held it; and the governors were to invest the money thus received in the purchase of messuages, lands, and other estates of inheritance, that there might be a perpetual provision for the maintenance and cure of the sick poor, and for defraying all other expenses of the Hospital.

Mr. Guy died on the 27th of December, 1724. The administration of the estate was attended with considerable difficulty, in consequence of the very numerous legacies and annuities to distant relations; and, although every diligence appears to have been used, and large sums were at once made available for the prosecution of Mr. Guy's intentions in completing the buildings, and bringing the charity (which, at the time of his death, provided 60 beds) into operation, about seven years elapsed before the proceeds were considered as realized. In October, 1732, an account was opened in the name of the president and governors, and the sum of £220,134. 2s. 7½d., was carried over to it as the balance of Mr. Guy's estate.

The act of Parliament which Mr. Guy had desired in his will should, if possible, be obtained for the incorporation of the governing body of the Hospital, was passed in 1725; and, with no important alteration, the wishes expressed by him were complied with in its enactments. The number of governors being limited to 60, it was enacted, that in case the number should at any time, in consequence of the neglect of filling up such vacancies as might occur, or from any other circumstances, not amount to 40, it should be lawful for the Lord Chancellor, or Lord Keeper, or Lords Commissioners of the Great Seal, the Chief Justices of the King's Bench and Common Pleas, and the Chief Baron of the Exchequer for the time being, or any two of them, at the request of any five or more of the members or governors, to nominate as many fit persons as should, together with the others, make up the number of 50 governors; and that such persons should thenceforward be deemed governors to all intents and purposes.

The first general court of the president and governors, under the provisions of the act, was held 5th of April, 1725; and, on the 21st of the same month, the physicians, surgeons, and clerk to the new hospital, were elected, and it was referred to the court of committee to prepare by-laws for the management of the institution.

Funds of the Hospital.—The proceeds of

Mr. Guy's bequest have been invested, at different times, in the purchase of real estates in the counties of Essex, Hereford, and Lincoln. Extensive purchases have also been made, at a more recent period, of freehold and leasehold property in the vicinity of the hospital; the cost of which has been, in great measure, defrayed out of a very large bequest made, in 1829, by William Hunt, Esq.

That gentleman, who during his life took great interest in the prosperity of the institution, and had actively co-operated with Mr. Harrison, the treasurer, in his plans for its improvement and extension (many of the purchases and alterations in the neighbourhood being made with his approbation, and in anticipation of the legacy which he had confidentially signified to the treasurer that it was his intention to make), by his will, dated December 1, 1825, and proved in 1829, after various specific and pecuniary bequests and annuities, and after bequests of 1000*l.* each to St. Thomas's Hospital, the Refuge for the Destitute, and the Philanthropic Society, left to his executors, Benjamin Harrison, John Benjamin Heath, and Fuller Farr, and their executors, &c. all his personal estates and effects whatsoever, and all such stock in the funds as he should possess at his decease, in trust to pay, assign, and transfer to the president, treasurer, and governors of Guy's Hospital. The only desire expressed in the will, relative to the mode in which the money should be disposed of by the governors of the hospital, was, that additional buildings and other conveniences should be supplied, for the reception of 100 more persons than were provided for by Mr. Guy.

The residue of Mr. Hunt's estate, paid over to the hospital as stated in the Abstract of the Accounts for the year ending March 25, 1831, consisted of

75,000 <i>l.</i> 3 per cent. consols.
60,000 <i>l.</i> „ reduced.
60,000 <i>l.</i> new 3½ per cent.
9140 <i>l.</i> 2 <i>s.</i> 3 <i>d.</i> cash.

The stock was valued at 186,675*l.*; thus making an amount of 196,115*l.* 2*s.* 3*d.* sterling. The annuities were valued at 2725*l.* 5*s.* 1*d.*; leaving a clear sum of 193,389*l.* 17*s.* 2*d.* applicable to the purposes of the charity.

The other benefactions to the hospital have amounted to little more than 10,000*l.*

The following is a summary of the possessions and income of the hospital in 1835, and of the annual payments under the wills of Mr. Guy and Mr. Hunt:—

	£.	s.	d.
Bardfield estate (Essex)	2687	18	11
Beaumont do. do.	2321	19	10
Leeze Priory do. do.	2778	8	3

Lincolnshire estates	7278	19	0
Southwark estates	2298	9	4
Fee Farm-rents from Dean } and Chapter of Rochester }	124	6	8
Annuity from the Stationers' } Company }	125	0	0
63,000 <i>l.</i> 3 per cent. consols. . . }	3690	0	0
60,000 <i>l.</i> 3 per cent. reduced } Casual profits in 1835 }	1005	17	5
Total gross income	29,677	17	1

Payments.

	£.	s.	d.
Annuity to Christ's } Hospital }	400		
Tamworth almshouses, 115			
Reserved for appren- } tices }	10		
Hunt's annuitants ..	230		
	755	0	0
Balance	28,922	17	4

On an average of six years, ending 1836, the income of the hospital was 30,491*l.* 1*s.*; and the out-going, for quit-rents, land-tax, building, repairs, and other incidental expenses, amounted to 9708*l.* 13*s.* 3¼*d.*: so that it appears that the clear annual income applicable to the special purposes of the charity, is nearly 21,000*l.* a-year.

Government of the Charity.

The number of governors is kept up as prescribed by act of parliament; election being made at a court of committees, where a majority of votes is sufficient. The present list of governors (Nov. 1835) includes 57 names. It is not the practice to fill up vacancies as they occur, and consequently several governors are usually chosen at the same court; a list being presented by the president or treasurer. No division has ever taken place; no donation is required, and the appointment is for life.

A general court is held annually, in November, when the election of the court of committees takes place; each governor giving in a list containing twenty-one names (exclusive of the president and treasurer), seven of whom must not be members of the existing court. At these several courts, the president, treasurer, auditors, and the physicians and surgeons, are chosen; and the presentations are made to the livings belonging to the corporation. Little other business is transacted at them, beyond the confirmation of the minutes of the courts of committees. The governors dine together, in the court-

room, in May and November; the expense, which does not exceed 50*l.* altogether, is defrayed by the hospital.

The committee of twenty-one meet, as occasion requires, for the despatch of business; eight members (of whom the president or treasurer must be one) form a quorum. There are no sub-committees. None of the governors derive any emolument or perquisite whatever from the office, except the treasurer, for whom a commodious residence is provided in the hospital, with wash-house and stabling, and coals, beer, and candles for his servants. The only privilege they enjoy is the right of each, in his turn, to recommend a lunatic for admission to the hospital.

The officers of the establishment are as follows:—

The President, Mr. Justice Pattison. His duties are, to direct the holding of the courts and committees when he shall see fit, and to preside at the councils, and exercise a general superintendence. His duties have, however, for some time devolved upon the treasurer.

The Treasurer, Benjamin Harrison, Esq. succeeded his father in the office in 1797; having previously passed twelve years with him in the hospital. Though no longer resident within its walls, he attends for several hours daily, Sundays only excepted. The management of the estates and revenues is in his hands, and he examines in person into the most minute details of every branch of the establishment; and the governors have been principally influenced by his advice in the various additions which have been lately made to those in London. No salary is attached to the office. Ten guineas are allowed for postage and parcels, and two guineas for petty expenses. No security is required from him. No banker is appointed for the hospital, and the account is kept in the treasurer's private name; but it is not at this institution as at many others, a recognized mode of remunerating this officer to allow him to retain large balances in hand; on the contrary, the hospital, prior to Mr. Hunt's bequest, was usually indebted to the treasurer, or the balance in his hands was not more at any time than 400*l.* or 500*l.*, except on one occasion, when a balance between 7000*l.* and 10,000*l.* was standing to his credit for about three weeks, in consequence of an unexpected delay in the completion of a purchase; and at this time the hospital was indebted to him upon a loan of 16,000*l.* All permanent advances of this description are reported to the committee, and, in these cases, interest at 5 per cent. has been carried to the credit of the treasurer; but it has frequently happened, that for short periods he has been in ad-

vance to the hospital, without the allowance of any interest at all.

Every article of expenditure is under the control of Mr. Harrison. He makes the larger payments on account of the hospital himself, the smaller demands being discharged by the steward, who receives cheques from him for the purpose. He appoints the sisters and servants of the institution, and regulates the attendance of the medical and surgical officers. The schools are exclusively under his control.

The other officers, the registrar or clerk, the chaplain, the steward, clerk of the works, &c. are similar to those at St. Bartholomew's and St. Thomas's (see preceding numbers), and their duties are nearly the same.

The officers and servants of the medical establishment are, three principal physicians, three principal surgeons, a consulting surgeon, assistant-physician, assistant-surgeon, accoucheur, surgeon-dentist, apothecary, matron and assistant, surgery-man and assistant, keeper of the museum, janitor, 24 sisters, and 24 nurses.

Two days in each week are fixed for the attendance of the physicians and surgeons, and in each week one of each attends in rotation on the principal taking-in day. All the cases admitted by either the physician or surgeon on this the regular day of admission, as well as all cases of accident or emergency admitted on other days during his week of duty, remain under his exclusive care while in the Hospital. The surgeon of the week also attends daily in the wards at half-past 12 o'clock. It was stated that in practice the attendance of the medical officers is much more frequent than is actually required of them by the regulations of the Hospital, each visiting his own patients as often as the urgency of the case requires; and it rarely happens that for several days after his taking-in day, any of them are absent for twenty-four hours together: the hospital is frequently visited by them all in the course of the same day.

The salaries paid by the hospital funds remain at the same amount (40*l.*), at which they were fixed in 1725; the only pecuniary emolument worth consideration being derived from the fees of pupils admitted to the practice of the hospital or to attend the lectures.

The assistant-physician receives no salary from the Hospital, but a payment is made by the treasurer from the pupils' fund, on account of chemical lectures given by him. Besides attendance on the out-patients every Friday at 11 o'clock, he in general visits the hospital daily, and attends to the patients of any of the physicians who chance to be absent, and occasionally supplies their places on the admission day.

The duties of the assistant-surgeon are nearly analogous to those of the assistant-physician: he is required to give immediate attendance in all cases of accident or emergency, and, if necessary, to see every surgical patient in the absence of the surgeon of the week: he lives in the immediate neighbourhood of the hospital. He receives at present no remuneration beyond 150*l.* a year, paid by the treasurer from the pupils' fund.

The time spent by the medical officers on their visits varies according to circumstances: nearly four hours are usually required to go round the house.

Each surgeon is permitted to select from his pupils four persons to be dressers: they are not chosen for talents or proficiency, but in consideration of the payment of an additional fee, usually fifty guineas for 12 months. Three of them are in constant attendance at the hospital, where rooms are provided for their residence. Their duties are to dress wounds, and to do whatever else may be necessary for the patient till the arrival of the surgeon or assistant-surgeon.

The consulting surgeon is consulted by the surgeons in all cases of danger or difficulty, and advises upon the expediency of proposed operations. The ordinary period of his attendance is on Tuesday in each week. He receives no salary.

The accoucheur and dentist are both lecturers in the medical school, and are appointed by the treasurer without consultation with any of the other governors.

The apothecary, besides the ordinary duties of his office in dispensing medicines and superintending the laboratory, visits the wards daily; and in the absence of the physicians and surgeons, attends to the medical patients, and the medical treatment of surgical cases. He is present at the general taking-in, and advises on the reception of other cases in the week; he never leaves the hospital without notice; nor for three or four hours without permission from the treasurer; he is not allowed to practise on his own account: he purchases the drugs under the direction of the treasurer; those of smaller consumption from three or four druggists; those of which larger quantities are required, in the market through the agency of drug-brokers, or at wholesale houses: his salary is 300*l.* a year from the hospital funds.

The surgery-man and cupper receives 90*l.* a year and has a residence in the hospital. All the surgical instruments are in his charge, and he has to be present at all operations; he cups both in and out-patients to the amount of about 5000 in a year.

The keeper of the Museum, with a salary

of 78*l.* a year, has the charge of the schools, the museum, and the anatomical preparations.

The janitor, with the same salary, attends the various lectures and operations, and accompanies the physicians and surgeons to the wards in clinical time, to prevent the intrusion of unprivileged persons; he regulates the admission of visitors to the patients, and is called in in all cases of irregularity or disturbance.

The matron performs all the same duties which are assigned to that office in other hospitals, having the charge of all linen and furniture, the general superintendence of all the wards, and the hiring and dismissal of nurses; her salary is 100*l.* a year, and a house in the immediate neighbourhood of the hospital is provided for her.

Of the sisters, one is attached to each ward for the general care of the patients and the superintendence of the nurses; rooms are provided for them as in other hospitals, contiguous to their several wards; their average wages are 50*l.* a year. They are usually selected from a higher class of females than the nurses, and are frequently widows in reduced circumstances.

The nurses are paid on an average 30*l.* a year.

Admission and Management of Patients.—The admissions are quite independent of character—all comers being received. Security from a householder for the burial of patients in case of death was formerly required, but is now seldom asked for, and the removal of this restriction has greatly extended the benefit of the charity among the poorer classes: for pauper patients 9*l.* a day is required from the overseers of their respective parishes, but the payments of these demands is made with great reluctance, and is very generally evaded. Sailors belonging to the Royal Navy, if their cases are sufficiently urgent, are received on a recommendation from the Board of Admiralty: the expenses incurred for washing being defrayed by the Victualling Board. Pregnant women are not admitted, unless under peculiar circumstances; and lunatics, (with the exception of the limited number of incurables who are received in accordance with the will of the founder,) are also inadmissible. No diseases on grounds of exclusion, except those reputed epidemic (contagious?), and for these, as in the case of the cholera, separate wards are prepared for such cases as may occur in the hospital.

Wednesday is the regular "Taking-in Day" in each week. Applicants must be present before ten in the morning: on their arrival they hand in printed petitions, furnished by the hospital, which are then filled up by the steward's clerk from the

information of the party, with the name and age, the nature and standing of the disease of the applicant. These petitions being then divided according to the medical or surgical nature of each case, each applicant is examined separately by the physician or surgeon of the week. The petitions are then marked by the examining officers according to their respective urgency: those which are extremely pressing are admitted instantly; the others are taken to the steward, and arranged by him according to the marks indicating their urgency; and when all are examined, the treasurer and governors, if any happen to be present, admit as many as will fill the vacant beds. The average number of applicants, in the six years preceeding the inquiry, was 94 weekly, of whom, on an average, 41 were admitted; but this does not include many who applied with disorders too slight to afford them a chance of admission. Those who are rejected for want of room are prescribed for at once, and, if necessary, made out-patients. Accidents and all other cases of sufficient urgency are admitted on other days as well as Wednesdays; and the average number of such cases appears to be 18 per week. For obstetric cases, ten beds are set apart. For eye cases, eleven beds are appropriated in one ward for females, and sixteen in another for males. No other classification of cases is made, except that syphilitic cases are placed in separate wards.

The average number of patients admitted annually (1830-1837,) is nearly 2400.

The total number of beds in the hospital is 538, though, on an emergency, 600 could be at once fitted up. These are disposed as follows:—

1 male accident ward	24 beds.
1 female do.	15
1 for venereal women	20
1 for venereal men	35
2 for surgical cases exclusively	66
12 for general purposes	290
1 for male eye cases	16
1 for female do.	11
1 for convalescent patients ...	10
1 for obstetric cases.....	10
1 for patients requiring to be kept apart from others	7
For patients infested with vermin, or nearly insane, or in a state of frenzy	10
2 galleries for incurable female lunatics, each of whom has a separate sleeping-room adjacent to the gallery	24
	<hr/>
	538

Two wards (one for each sex) are set apart in each year for the reception of clinical cases, which are selected in consequence of symptoms indicating the neces-

sity of constant and extreme watchfulness, or because they are likely to prove interesting and instructive. The clinical lecturer attends daily in these wards with his pupils, and makes observations on each case as he visits it. Those patients to whom absolute repose is necessary are passed by, and the patients in general are not incommoded by the visit, their health and comfort being considered in preference to the success or utility of the lecture. Two pupils, appointed by the clinical lecturer, take in rotation to attend in the clinical wards from ten in the morning till the evening; and a discretion is given them to vary the quantity of medicine prescribed, or to suspend the administration of them.

A Clinical Report Society has been lately formed among the pupils of the house, with the approbation of the treasurer. Reporters are assigned to each ward, and the clinical reports of nearly every case are made by them. The first annual report was made in 1837, when the cases brought under the notice of the society were as follows:—

1037 entered in a tabular form
1264 completely transcribed in a tabular form
174 detailed at length

2475

The out-patients may be divided into four classes. Of medical and surgical cases of a general character, the former are admitted as out-patients on Fridays; the latter, on Thursdays. They receive, on application, a printed form, which remains in force for four weeks, but has been, in some instances, extended to ten months. They attend at the hospital on the same day of the week as that on which they were admitted, and are furnished with medicines: they are also, if necessary, seen on Tuesdays by the medical officers who happen to be present. They are taken into the hospital when their cases are sufficiently urgent to require it, and, when there, they remain under the care of the assistant surgeon or physician, and are placed in wards which are usually filled entirely with patients thus admitted.

Out patients, with diseases of the eye, are admitted on three days in each week. Operations are usually performed on Thursdays.

Obstetric out-patients are persons whose pregnancy or confinement is attended with disease. They attend on four days in the week, and, when necessary, are admitted into the hospital under the care of the physician-accoucheur.

Lying-in cases, in which poor married women are attended at their own houses: a previous personal application is necessary at the lying-in office in the hos-

pital, where one of the sisters is appointed to attend for the purpose. An inquiry is made into the case before any assistance is afforded. Medicine and occasional diet are afforded to them. They are attended by the lecturer on midwifery and his assistants.

Dental cases are attended to on Fridays.

The following statement, furnished by the treasurer, gives the nearest approximation that can be made to the number of out-patients:—

	per ann.
60 surgical tickets issued per week, amounting to	3120
80 surgical casualties per day, estimated at	24000
30 eye cases per week	1560
90 physicians' tickets per week ..	4680
6 cases per day relieved at the apothecary's shop	1800
20 obstetric cases per week	1040
30 lying-in cases per week	1560
Total	37,760

Hospital accounts.—The receipts of the hospital have been already mentioned in detail, and the average, available for the purposes of the charity, shewn to be nearly 21000*l.* a year. Among the disbursements, the most important items among the hospital expenses, taking the average of ten years, for each of which the exact sums are stated as follows:—

Rent, taxes, rates, &c. about	£1200
Repairs	2500
Officers' salaries and servants' wages ..	5560
Fuel, lighting, soap, and water	1500
Medicines	3100
Tradesmen's bills for provisions ..	4500
Furniture and washing, about	1400
Stationery, printing, &c.	150
Petty expenses of treasurer, steward, and matron	40

The annual balance in the treasurer's hands, if any at all exist, is not more than sufficient to meet immediate current expenses, and varies usually from four to five hundred pounds, the whole actual income being expended for the purposes above-mentioned, and for some others of less importance, and less constant amount.

The following table is given of the average daily cost of each patient:—

Provisions, &c., including bedding, soap, water, linen, washing, and medicine	s. d.
Lodging, including rent of leasehold, taxes, &c.	0 2.16
Salaries, servants' wages, &c.	0 8.44
Incidental expenses	0 3.67
Law expenses	0 1.18
Total	2 6.10

Medical Schools.—It appears by an entry

in the minute books, dated Feb. 26, 1760, that an arrangement was at that time entered into with the governors of St. Thomas's Hospital for extending the privilege of attending the practice of each establishment to the pupils of both. This was further regulated by some resolutions passed in November 1768, and for many years the advantages thus offered were reciprocal.

Medical lectures only were delivered at Guy's, while surgery, together with anatomy, were taught at St. Thomas's, and the profits arising from the pupils' fees were divided between the lecturers of the two institutions. A close connection was thus established between the houses, and the officers of the one were frequently appointed lecturers at the other. For many years, Sir Astley Cooper, who was surgeon at Guy's Hospital, was lecturer in the anatomical school of St. Thomas's. In 1825, a dispute arose between the hospitals respecting the appointment of a demonstrator and under-lecturer at St. Thomas's; and it was then resolved, that the means of surgical education should be provided within the precincts of Guy's Hospital. The schools, museum, &c., were therefore built, and Sir A. Cooper appointed lecturer on surgery; he was desirous of giving his anatomical collection, then deposited at St. Thomas's, to Guy's, but the former establishment refused to surrender it, but ultimately gave Sir A. Cooper 1000*l.* for his interest in it, which sum he presented to the new medical school of Guy's.

For the building of the schools 7000*l.* were advanced by the treasurer. The interest for the first year was paid from the funds arising from pupils' fees. From that time to 1830, it was paid from the hospital funds; and in that year the principal was repaid out of Mr. Hunt's legacy, with whose approbation the building had been erected. Altogether, about 8000*l.* has been paid from the hospital funds for the establishment of the schools and museum, which are also kept in repair from the same source. Since their completion, a very valuable collection of models and preparations has been formed at the cost of the funds of the medical and surgical school, which, being made the actual property of the hospital, may in some degree be considered as a remuneration to the charity for the sums expended on the building.

Excepting so far as regards the prime cost and repairs of the building, and the salary of the keeper, the schools are wholly independent of the funds of the foundation. The pupils' fees for attendance on the hospital practice and the lectures are paid into the hands of the treasurer, and the governors have implicitly and wholly delegated to him, not in his official capacity, but as a private individual, the ma-

nagement of the schools and museum, reserving to themselves only the power of withdrawing the permission to use the building for its present purposes.

From these funds, after deducting the expenses of attendants, &c., for the lectures, 150*l.* a-year is allowed to the assistant surgeon, and salaries are paid to the modeller, and the anatomical draughtsman and his assistants. The lecturers are selected and appointed, and the amount of fees paid by the pupils determined by Mr. Harrison alone, who likewise regulates the mode and proportion in which each gentleman is to be remunerated for the instructions which he affords. The accounts of this fund are wholly unconnected with those of the hospital, and are in the private possession of Mr. Harrison.

General Remarks.—These include brief statements of the principal arguments which are commonly advanced on the comparative merits of the plan adopted in some continental hospitals, of appointing a single medical officer with a remunerating salary and competent paid assistants to reside within the walls, and devote his whole time to the hospital, abstaining from private practice, and of the system of this and most or all other hospitals in this country, where the salaries from the funds of the charity are trifling and the indirect advantages and the pecuniary profits from the schools considerable. There are also added the arguments in a few words for and against the system of admitting many patients on but one day in each week; but no decided opinion is expressed on either of these points, though the feeling of the commissioners seems to incline to the continuance of the present system.

The existence of the schools, independently of the profit which the medical officers receive from them, is mentioned as highly beneficial to the charity, by making the officers of the establishment feel that, under the scrutiny of competent judges among the pupils, their reputation is constantly at stake. With regard to the clinical pupils also, it is remarked, that besides the good resulting to medical science, it is obvious that the objects of the charity are greatly promoted by the constant presence of young men, whose medical attainments render them more capable of judging of the progress of disorders than ordinary nurses.

Some observations are made on the management of the lunatic patients, in which it is submitted that a very considerable improvement might be made, and the report closes with the remarks upon the powers exerted by the treasurer, which were quoted in the number of this journal for March 13th, p. 922.

FRACTURE OF THE LEG; WITH SOME PECULIAR CIRCUMSTANCES.

To the Editor of the Medical Gazette.

SIR,

I BEG leave to transmit the particulars of the enclosed rather interesting case for insertion in your journal.—I am, sir,
Your obedient servant,

GEORGE BUSK.

S. H. S. Dreadnought.
March 16, 1840.

Mr. J. æt. 65, of stout habit, had been more or less paralytic for upwards of twenty years, for the last twelve or fourteen of which he had been completely deprived of all power of motion and sensibility, from the loins downwards. The bowels were habitually constipated, and the feces and urine were passed unconsciously.

The lower extremities were small, from deficiency of muscular substance, but otherwise fat, and in good state of nutrition. There was occasionally slight spasmodic motion in the legs and feet. On the 10th of January, 1840, he went on business, travelling as he usually did in a spring-cart, into and out of which it was necessary to lift him, as he had no power whatever of spontaneous locomotion.

On his retiring to bed, after returning from this expedition, his servant, when undressing him, noticed an unusual flexibility in the left leg, and observed to her master that she thought it was broken; he, at first, did not believe her, but soon ascertained by moving and bending the limb, that such was really the case. He was, however, unable to account for this injury, of which he had been perfectly unconscious, till the discovery was made by his servant.

It is probable that the accident happened upon one of the occasions of his being lifted into or out of the cart. As it was late at night, he deferred sending for surgical aid till the morning, when Mr. Allinson, Surgeon, Woolwich, was summoned, who on his arrival, about 10 A.M. found the limb presenting a very formidable aspect. It was much deformed, from having been allowed to lie on the bed without any support, in consequence of which the foot was turned completely outwards. The tibia and fibula were broken rather below the middle, and the fractured ends much displaced, from the malposition of the

foot; there was, however, no retraction, owing to the paralysed condition of the muscles. The leg, from the knee downwards, was enormously swollen, of a deep purple colour, and the surface covered with large vesications, filled with a red sanies. There was not the least pain nor any sensibility in the limb, but there was frequent spasmodic twitching of the muscles. Mr. Allinson requesting my assistance, I saw the patient in the afternoon of the same day, at which time the swelling had greatly subsided, but the limb was otherwise in the condition above described, and I ascertained beyond a doubt that no reflex motions could be excited in either limb by irritation of the soles of the feet, or other part of the surface. The spasmodic twitching was frequent, but trifling in extent.

The appearance of the limb evidently indicated great effusion of blood into its textures, and there was probably extensive laceration of the soft parts around the fracture, in consequence of the repeated and rough motions to which the limb had been subjected, doubtless for some time after the infliction of the injury. Under these circumstances the fate of the leg appeared rather doubtful. However, we determined upon the attempt to save it if possible. The leg, surrounded with a many-tailed bandage, was placed on a pillow, and supported by a wooden splint on either side. The bandage was kept constantly wet with camphorated spirit lotion, and as every thing appeared to go on well, the applications were not disturbed for a week, when it was found that the swelling had fallen very considerably, and the colour and general aspect of the limb were much improved. The same plan was pursued for another week, by which time the swelling and redness had nearly disappeared, and the fracture was less loose. As it was necessary to move the patient frequently to prevent excoriation of the nates, upon which he constantly sat, it became advisable to treat the limb so as to allow of his being readily moved. Consequently the leg was covered with layers of lint dipped in mucilage, and a bandage applied, which in a day or two formed a sufficiently hard case to allow the limb and body to be moved freely without danger of displacing the fracture.

Mr. J. about this time became very unwell; he had a troublesome cough, and

could not sleep at nights, and appeared to labour under very considerable constitutional disturbance, the cause of which, however, was not very manifest, as it could not be referred in any degree to the state of the leg, which never afforded any uneasiness.

On my next visit, about three weeks afterwards, I removed the gum splint, which had not been disturbed from the time of its first application, and I found the bones to be firmly united, without any deformity. The appearance of the leg was quite natural. Mr. J., however, was very ill, and was much reduced by extensive sloughing of the nates, although he suffered no pain, sensibility in those parts being as completely annihilated as in the legs. This sloughing, in spite of the greatest care, continued to extend, and the constitutional disturbance to increase; all nourishment was refused or rejected, and he died on the 5th March.

Unfortunately no inspection of the body was allowed—a circumstance much to be regretted, as it would have been extremely interesting to examine the exact pathological condition of the spinal cord and nerves, in a case where paralysis was so complete, and the power of nutrition and reparation so little impaired. From the absence, however, of all reflex phenomena, and the extent of the paralysis, it may probably be concluded that the lesion was in great measure confined to the nerves constituting the *cauda equina*, and did not implicate any considerable portion of the spine itself.

The slight spasmodic twitching to which the limbs are subject, could hardly be referred to the reflex function of the cord, as direct irritation of the surface had certainly no influence in producing muscular contraction.

The more active movement, which occurred in the injured limb, may readily be explained by the supposition that the torn muscles were directly irritated by the fractured bones.

CUBEBS IN BRONCHITIS.

To the Editor of the Medical Gazette.

SIR,

In a late number of your valuable periodical, I perused with much pleasure, a powerful testimony from the pen of Mr.

Blake, to the efficacy of cubebs in restoring the healthy tone and functions of the schneiderian membrane, in a case of inveterate and confirmed coryza.

I have, during the last two years, been in the frequent habit of prescribing the same drug with great advantage in cases of chronic bronchitis and dysentery. As an illustration of its excellent operation in controlling the former disease, permit me to draw attention to the following case. A. S. æt. 31, had, for a long time previous to consulting me, suffered from the effects of a severe cold, caught, consecutively to some eruptive disease, three winters since. The following were the symptoms, as taken from my notes, when I first prescribed the remedy in question: considerable emaciation, with a carriage and manner expressive of great prostration of strength: a frequent and almost habitual cough, most urgent towards the morning, attended with profuse expectoration of opaque, greenish, muco-purulent matter, mixed with a colourless, watery phlegm, in which the colouring matter of the blood had been occasionally observed. The breathing wheezing and oppressed, particularly after exertion, with scarcely any pain in the chest. Respiration sometimes louder, at other times more obscure than natural, accompanied with the *mucous rhonchus*, with the occasional occurrence of *sibilous* and *sonorous* rhonchi, indicative of partial obstruction of the tubes; but after many examinations, there could be detected neither constant absence of the respiratory murmur, nor pectoriloquy, nor any marked defect of resonance upon percussion. In addition, there were present evidences of slight derangement of the digestive organs. Having convinced myself of the absence of tubercular disease, I immediately resolved upon the exhibition of cubebs, with the view of modifying and ultimately checking the morbid secretions of the diseased mucous surface, and with the happiest results. A marked improvement was speedily discernible in the character and quantity of the sputa, which, with the cough, finally ceased, leaving my patient, in her own animated language, to "enjoy a new lease of life." The treatment was aided by the use of the linimentum ammoniæ as an external counter-irritant, by a change of residence to the southern coast of Devonshire, and by strict attention to regimen and exercise.

Several similar cases might be mentioned as corroborative of the efficacy of cubebs in chronic catarrhal discharges from mucous membranes, but I feel that as a young practitioner it would be immodest to obtrude the results of a very limited experience upon the profession. The foregoing case was, however, so well marked in its results, that I cannot refrain from transmitting this brief notice to the *MEDICAL GAZETTE*, in order that it may be appended as additional evidence to the truth of Mr. Blake's remarks.—Your obedient servant,

JOSEPH B. GRAY.

Duke Street, Chelmsford.

April 2, 1840.

FATAL CASES

OF

OBSTRUCTION AND ENORMOUS DISTENSION OF THE BELLY,

Arising from a peculiar Conformation of the Colon.*

BY ANDREW BUCHANAN, M.D.,

Professor of the Institutes of Medicine in the University of Glasgow.

(With 12 Figures in illustration.)

I PROPOSE, here, to lay before you some observations upon a very rare disease, of which it has been my fortune to meet with three cases. This disease is attended with symptoms which are quite peculiar and distinctive. It produces as much acute suffering as any of the most formidable diseases to which the human species is subject; and, notwithstanding the most powerful means employed to arrest its progress, it has invariably gone on to a fatal termination. It is, farther, interesting to the medical inquirer, from being a disease not generally known, and of which the true nature has not, as appears to me, been hitherto understood.

It will be seen, from the remarks which follow, that the disease in question is always attended with, and, according to my view, is necessarily dependent upon, a peculiar primordial formation of the colon, which, to avoid

* In August last we published an interesting paper, by Dr. Buchanan, on certain peculiarities in the distribution of the colon, but unfortunately without the engravings which ought to have accompanied it. We are now, however, enabled to give these; and they appear to us so curious, that we have thought the best plan, under the circumstances, was to reinsert the text, without which, indeed, they would be unintelligible.—ED. GAZ.

interruption hereafter, I shall commence by describing.

The colon is more subject than any other part of the intestinal canal to vary in length and in mode of disposition; or, which comprehends both, in the course which it follows through the abdomen. Upwards of twenty examples of such variations will be found recorded in the works of Morgagni. The most common of these variations is that observed in the transverse arch of the colon, which, instead of running straight from right to left, immediately under the liver and stomach, is incurvated downwards, so as to reach the umbilicus*, or even the urinary bladder†. Morgagni has recorded an example of the right colon not running straight from the iliac to the hypochondriac region, as it usually does, but instead, being so much inflected that the cæcum was in contact with the transverse arch of the colon under the liver‡. The same author likewise describes a case in which the colon, after observing its usual course as far as the stomach, passed thence right down to the sacrum, in front of the small bowels§. A case will be narrated hereafter, in which the colon, after arriving by the usual route at the left kidney, passed thence to the umbilicus, and from that point right downward, between the tract of the recti muscles, to terminate in the rectum. A double variation in the course of the colon was, in one instance, observed by Morgagni, the transverse arch being inflected downwards; and, further, the left colon, after reaching the kidney, returning to the left hypochondrium, and passing thence obliquely towards the sacrum||. Instances are not unfrequent of the sigmoid portion of the colon deviating from its usual course. It sometimes passes from the left groin across the fundus of the bladder to the right groin, and thence ascending and turning to the left, it goes over the top of the sacrum to form the rectum¶. This is, indeed, described by Glisson as the

usual course of this portion of the colon*. A case is described by Morgagni, in which the sigmoid flexure of the colon lay almost completely in the umbilical region of the abdomen†.

These examples are here adduced, not merely to show how much the colon is liable to vary in its course, but because a knowledge of such varieties is of high importance to the physician, who, if ignorant of them, would, as has been remarked by Morgagni, be apt to fall into error in estimating the seat of many affections of the intestines. There is, however, only one of the varieties enumerated above which has been known to produce a disease at all analogous to that which I am about to describe.

The only variety of conformation in the colon which remains to be mentioned, is of the same kind as the two last enumerated; but I have kept it separate, from its constituting the most common predisponent cause of the disease to be here treated of. That it is a rare variety must be obvious from the circumstance of its having escaped the diligent research of Morgagni‡. While, however, it is very rare in Italy, it may probably be much more common among the inhabitants of the British isles: at all events, within a period of little more than seventeen years, seven examples of this variety of conformation have been observed in Scotland; five of them in Glasgow, and two in Edinburgh; but the individuals in whom they were observed were not all natives of Scotland. Of these seven cases, I have myself seen four. The first I saw was in the year 1819; but in it, and in the two next cases which occurred to me, the peculiar disease arising from this formation of the colon had been induced, and I shall not, therefore, anticipate the history of them. In the spring of the year 1832, in examining the body of a patient who died of cholera, I met with an example of the same formation of the colon, which had not excited any similar disease.

A case of exactly the same kind occurred to Dr. Hunter, Andersonian Professor of Anatomy, in 1831§. The

colon observed its usual course as far as the left groin, when it again ascended as high as the transverse arch immediately under the liver, and then, turning to the right side, it descended into the pelvis. This was exactly the disposition of parts observed by myself, in the case occurring in 1832; and, in both of these cases, it is worthy of remark that the colon entered the pelvis upon the right side of that cavity. In other cases, however, as will be seen hereafter, the colon descended into the pelvis, as usual, over the promontory of the sacrum; and, in one very remarkable case, the colon, crossing from the left to the right groin, ascended parallel to the right colon, and then, turning to the left, descended near the mesial line of the body into the pelvis.

The following more particular account of the form and connections of the colon in the patient carried off by cholera, I extract from my note-book, where it has for title, "Anomalous Distribution of the Sigmoid Flexure of the Colon." The sigmoid flexure of the colon, instead of lying in the left iliac region, and having its meso-colon attached to the left side of the pelvis, stretched obliquely across in front of the small bowels, in the direction of and nearly as high as the gall-bladder. It then turned so as to form an acute angle, and, passing down parallel to the ascending colon, it entered the pelvis on the right side, to form the rectum. Where the colon entered the pelvis, it was attached to the right side of that cavity by a fold of the peritoneum, exactly as is usually seen on the opposite side: the remaining portion of it was kept in *situ* by a very unusual attachment, the omentum supplying the place of meso-colon. The left side of the omentum lay free as usual, on the surface of the small bowels; but the part arising from the right half of the transverse arch, and also that coming from the right colon, embraced the contiguous portion of the sigmoid flexure, and, descending from its inferior edge, terminated by a well-defined margin, at the brim of the pelvis. In consequence of this disposition of parts, the omentum did not admit of being lifted up, as usual, except on the left side; its attachment to the sigmoid flexure prevented it from being raised on the right side, but the hand could be passed between these parts and the small bowels,

showing that there was no adhesion of any kind between them.

Of the deviations from the usual conformation of the colon described above, those occurring at the proximal or middle portions of the intestine do not appear to be productive of any disease or inconvenience to the individuals so constituted*. On the other hand, the deviations which occur at the distal extremity of the colon have been, in several instances, found to accompany a very severe disease, which, so far as I know, has never been observed when the colon was of the usual conformation, and of which, therefore, the abnormal conformation of the colon must be considered as most probably the cause. Of this disease, the first example which I had an opportunity of witnessing occurred in the spring of 1819, and was treated by Dr. Andrew Duncan, jun., in the clinical wards of the Edinburgh Infirmary. The next case occurred about two years afterwards, in the Glasgow Infirmary, where I was, at the time, house-surgeon. This case, in the absence of the attending physician, was chiefly treated by Dr. Lawrie, then one of the physician's clerks. The third, and only other case which I have seen, came under my own care in the year 1825.

In all of these cases I believe the disease to have been essentially the same; the leading symptoms and appearances on dissection, being very little different, although, as will be seen hereafter, there is some room for difference of opinion as to the precise mode in which the disease originated.

In attempting to sketch the history of this affection, I shall chiefly refer to the case last mentioned; as I am more intimately acquainted with it than with the other two, in consequence of my having attended the patient during the whole course of his complaint, and examined his body after death.

James Connell, apparently from forty to fifty years of age, residing in Stockwell Street, came under my care towards the end of June 1825. He had been long subject to constipation of the bowels, but never to such a degree as to injure his health, which had been tolerably good. For some time previous to my seeing him, his bowels had been more confined than usual, and he had been troubled with flatulency and swell-

* Morgagni, *Advers.* iii. *Animad.* 14.

ing of the belly. On examining the belly, I found it to be very much distended, and the swelling had all the characters of tympanites, being soft, elastic, and resounding on percussion. His pulse was not affected, and he complained only of the uneasy sensation occasioned by the flatulent distension of the belly. He was ordered a dose of calomel and jalap, which produced no effect. Castor oil, Epsom salts, senna, aloes, colocynth, scammony, and elaterium, were all tried successively, or in combination, but all to no purpose; not a particle of *fæces*, nor any flatus, was discharged. Injections, both simple and medicated, were alike unavailing. Among the latter employed were a strong solution of sulphate of magnesia, in an effusion of senna, and a solution containing six grains of tartar emetic. Not the least difficulty was experienced in throwing up the injections, but they came away, either immediately or soon after, without any admixture of *fæces*. On examining the rectum, it was found quite empty, as far up as the finger could reach, and very large in diameter. The patient's friends, of their own accord, introduced a common candle into the fundament, and pushed it as high up as they could get it to go; but not the least relief was procured from it. Meanwhile, the swelling of the belly went on increasing, till it was truly terrible to behold, being carried seemingly to the utmost possible point which the animal tissues could endure, without actually giving way. In this miserable condition the patient lay on his back, with his legs bent, and his knees drawn up, to avoid all stretching of the integuments of the abdomen. The only other posture he could endure was resting on his knees and elbows. When questioned, he complained only of the violent stretching of his belly, the pain of which seemed to swallow up all other feelings. His mental faculties continued unimpaired to the last. The respiration was slow, and as if impeded, most probably from the elevation and immobility of the diaphragm. His pulse was slow, and with a full steady beat. These characters of the pulse continued the last time I visited him, the day before his death, which took place about eight days from the time I first saw him, and about twelve from the last evacuation of his bowels.

The body was examined the day after the patient's death. On opening the cavity of the abdomen, the colon, enormously distended, and occupying an unusual situation, was the first, and indeed the only object which presented itself, all the other viscera being concealed behind its convolutions. Four immense bags were seen running nearly parallel to each other, and in the direction of the length of the body; while another similar one ran, at right angles to them, at the upper ends. So extraordinary was this appearance, that, notwithstanding my having seen two similar cases previously, it was only after tracing the colon from end to end that I became satisfied that I had, as yet, seen no other part of the intestines. The colon observed its usual course, till it reached the left iliac region, when it made a sweep to the right, passing behind the pubis, and returning across the lowermost lumbar vertebrae; it then ascended, till it came in contact with the transverse arch, when, turning to the right, it descended to the sacrum; thus forming the two middle bags above described. Every part of the intestine was greatly enlarged in diameter, but the enlargement was greatest at its lower end, where it was not less than from five to six inches in diameter. The upper part of the colon contained chiefly wind, the lower part only *fæces* of a yellowish white colour, and of the consistence of very soft mortar. On lifting up the folds of the colon, the small bowels were found inflated to the uttermost: the stomach was empty, and of its usual size. There was no effusion of fluid in the cavity of the abdomen, and the peritoneal covering of the bowels exhibited no traces of inflammation, although there was a good deal of engorgement in the veins of the mesentery. The prostate gland was much enlarged, and the dilated neck of the bladder contained upwards of twenty small angular calculi, consisting of uric acid.

It will naturally be asked, whether the examination of the body did not afford any explanation of the obstruction of the bowels? This subject I have deferred to the last, both on account of its importance, and because the obstruction in this case was ascertained to proceed from a cause quite different from that which has been assigned for it in all the other cases of this disease upon record.

In all these cases it was supposed that the obstruction proceeded from a twist of the colon, at the lower end of its sigmoid flexure. In the present case there was no twist, but there was a cause of obstruction more powerful than if the intestine had been (which I believe to be impossible) twisted completely round. To understand the nature of this obstruction, it is necessary to call to mind the description of the colon given above. After leaving the left iliac region, the colon crossed the mesial line of the body, behind the pubis: immediately returning, it ascended on the left side as high as the transverse arch, and then it descended on the right side, keeping in front of the inflated small intestines, till it turned back over the promontory of the sacrum, to be bound down to the anterior surface of that bone by the peritoneum. Now, just at the point where it turned backward, and was most pressed upon by the inflated small bowels from behind, it was crossed in front by the beginning of the ascending portion of its own sigmoid flexure. This last part of the intestine was very heavy; the whole lower part of the colon being, as stated above, filled with feces, and containing nothing else. The infarction commenced somewhat below the middle of the descending colon, and extended to within three or four inches from the end of the sigmoid flexure farther down than which the gut was completely empty. Now, what was it that arrested the descent of the feces at this point? It obviously was the compression of the lower end of the colon, between one of its own massy convolutions passing it in front, and the distended small intestines and inferior end of the vertebral column lying behind it. The compression was exactly of the same kind as though the gut had been pressed in a vice, or between two fingers placed parallel to each other, one before it, and the other behind. At the compressed part the two sides of the intestine were in contact; immediately below, it was quite empty; immediately above, it was more than five inches in diameter, and gorged with feces; and, on lifting up the anterior compressing portion, it left the mark of a quarter of a circle impressed upon the soft feculent mass in the portion behind. This quadrant was exactly the measure of the distance between the completely distended and the

collapsed part of the intestine. It was this remarkable impression upon the end of the colon that first attracted my attention, and, by leading me to examine how it was produced, discovered clearly the cause of the obstruction.

In the case which occurred while I was a student in the clinical wards of the Edinburgh Infirmary, in May 1819, the patient was a female, forty years of age. She had been long previously of a costive habit of body. During nine days preceding her admission to the hospital, nothing had been passed through her bowels, and the obstruction continued complete till her death, five days afterwards, notwithstanding the administration of the most powerful cathartics and injections. As in the case last detailed, no difficulty was experienced in throwing up the injections, and, on examining the rectum with the finger, it was found quite empty and unobstructed. The abdomen was distended to the uttermost, and the seat of a constant and most distressing pain: the swelling was of the tympanitic kind. The sufferings of the patient were much increased by whatever posture put the parietes of the abdomen upon the stretch, and some relief was obtained by relaxing them.

The appearances after death were very similar to those described above. The colon was enormously dilated, and so disposed as to conceal all the other abdominal viscera behind its convolutions. It exhibited two deviations from its normal course. As in the last case, after reaching the iliac region, it ascended as high as the transverse arch, and, turning to the right, descended nearly in the middle of the belly to form the rectum: this was the portion of the intestine most dilated. The other deviation consisted in an incurvation downward of the right half of the transverse arch. What added much to these remarkable appearances was, that the colon was in many places of a green colour, like the surface of stagnant water, owing, as was conjectured, to the contents of the intestine being visible through its attenuated coats. About a pound of sanguinolent serum was found in the peritoneal cavity, and there were marks of inflammation both on the large and small bowels. At the termination of the colon in the rectum, the intestine was observed by Dr. Duncan to be twisted from left to right, and this he

FIG. 5.—Tidicæus.

FIG. 3.—Morgagni.

FIG. 6.—Glisson.

supposed to be the cause of the obstruction of the bowels.

Of this case an account has been published, with permission of Dr. Duncan, in the 16th volume of the *Edinburgh Medical and Surgical Journal*, p. 384. To that account I am indebted for some of the particulars stated above.

The last case of this disease, of which, as above mentioned, I can speak from my own observation, occurred in the Glasgow Royal Infirmary in the year 1820 or 1821. I am unable to give the date with precision, having myself preserved no notes of the case; and, although Dr. Lawrie was kind enough to cause a diligent search to be made for the hospital journal, in which the history of it is recorded, his efforts was unsuccessful. The patient was a man of the name of Graham. His bowels had been in a state of obstinate constipation for some time before his admission into the hospital; the most powerful purgatives produced no effect in moving them: injections, and every other means which Dr. Lawrie could devise, were alike unavailing. Of these means, one deserves more particular mention, from its being singularly well adapted to the treatment of cases of this kind, and because it was many years afterwards brought forward as a new discovery in practical medicine. An œsophagus tube was introduced into the rectum as far up as it could be passed, and along this tube injections were thrown into the bowels, but no discharge of feces followed. The patient died after being in the hospital about eight days, and having suffered terribly from the pain in his belly, which was tympanitic, and distended to the utmost degree.

The dissection was performed by Dr. Laurie and myself, assisted by our common friend, Mr. Robert Smith, then apothecary to the infirmary. We found the colon much dilated along its whole extent, and more especially towards its lower end. The sigmoid flexure exhibited the same abnormal formation as in the two preceding cases, being much longer than usual, and lying chiefly in the umbilical region of the belly, in front of the small bowels, having its ascending portion on the left side, and its descending portion on the right. The only cause of the obstruction of the bowels which we could discover was a twist or rather fold of the intestine to one side, where the colon terminates in the rectum. I did not feel satisfied of

the adequacy of this cause to produce the effect ascribed to it, but I could discover none other. The small bowels were much inflated; there were no traces of peritoneal inflammation.

[The conclusion of this paper, with the other six figures, will be given in our next.]

CASE OF GLANDERS OR FARCY.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case worthy of a place in your valuable journal, I shall feel obliged by your giving it insertion. Whether it is to be considered as farcy or glanders, or farcy glanders, I will not take it upon myself to determine.

John Smith, æt. 30, was admitted into Pitcairn's Ward, St. Bartholomew's Hospital, January 23rd, with an indolent ulceration in the lower part of the left fore-arm, communicating with a fistulous passage, extending upwards between the muscles to a little above the elbow-joint. From this sinus there was discharged a quantity of unhealthy-looking pus, the man being evidently in a bad state of health.

States that he is a knacker by trade; that, about six months previous to his admission, he ran a splinter into his finger, of which, at the time, he took but little heed, but continued his usual avocations. On the day after the receipt of the injury the finger began to be very painful and inflamed, the pain extending up the fore-arm and arm as high as the shoulder. In a few days matter formed in the finger, and the flexor-tendons sloughed. Soon after, another collection of matter occurred in the palm of the hand; and, subsequently to this, two other formations, one in the lower part of the fore-arm, and the other at the lower and inner part of the arm, just above the elbow joint. Was in the habit of taking large quantities of gin; in fact, a comrade of his, who was at the same time in the hospital, stated, that he never knew one of his age drink to such an extent. After the lapse of a few weeks, his friends noticed that he began to lose flesh, and decline in health; but he still continued his employment for nearly two months after the receipt of the injury. He became an out-door patient at the North London Hospital; had formations of

matter in the finger, which were opened, but re-formed. Whenever the parts began to heal, says he became much worse in health, and that the pains in the arm increased. On one occasion the abscess in the finger healed, but a fresh formation of matter took place in the lower part of the fore-arm. About four months ago was admitted into St. Bartholomew's. The abscess in the finger and hand healed, but that in the fore-arm and above the elbow still remained open. He was nearly two months in the institution; when being in a bad state of health, and the abscess showing no disposition to heal, it was thought advisable to make him an out-door patient; which he continued to be for a short time, and was re-admitted on the 23rd of January.

Poultices and warm fomentations were applied to the arm, and the compound senna draught administered *pro re nata*. This treatment was pursued for a few days; but the sinus showing no disposition to heal, it was laid open; at the same time a more generous diet was allowed, and two grains of the sulphate of quinine three times a-day,—sulphate of zinc lotion and water dressings to the wound. Under this treatment the parts assumed a more favourable aspect, the sinus contracted, and the discharge considerably lessened.

On the 19th of February,—that is, a few days after the wound began to heal,—the man complained of pain in the arm and shoulder, which, by the 20th, had extended up the side of the neck. In the course of the day he had a rigor, which lasted for a quarter of an hour or twenty minutes, and subsequently two other distinct attacks. On the following day complained of pain at the left angle of the lower jaw, in which situation the parts were swollen and indurated: leeches were applied and warm fomentations, besides internal remedies. On the following day complained of pain in opening his mouth: the swelling had extended over the angle of the jaw, and up the side of the face, taking the direction of the parotid gland. It (the swelling) was of a bright red shining appearance, indurated, and very painful on pressure; the leeches and fomentations were repeated, which, however, seemed to be of little or no benefit. The inflammation continued to extend, the palpebræ became involved and swollen, so as completely to close the left eye, from

which a thick puriform discharge took place. The swelling and induration gradually extended forwards to the side of the nose. The integuments covering the swelling assumed a livid appearance, and ulcerated at various points, which gave vent to small collections of matter presenting very much the character of carbuncle. The lips became very much swollen, and tubercular elevations formed on them, which rapidly passed into a state of ulceration. The mucous membrane lining the left cheek ulcerated, and portions of it sloughed; the disease extending backward to the posterior fauces. The patient was ordered strong beef-tea in addition to his other diet, port-wine, and the sulphate of quinine; a large linseed-meal poultice over the face, and the gargarisma sodæ chlorinatæ. Nothing, however, seemed to arrest the progress of the disease. He gradually passed into a low typhoid state; the breath became remarkably fetid, and was stated, by Mr. Charles Clark, an experienced veterinary surgeon, who saw the man two days before death, to resemble very much that of a glandered horse. Mr. Clark, also, immediately recognised the characters of the suppurative ulcers around the face and lips as similar to the peculiar appearance of farcy buds in horses. The tongue, the entire cavity of the mouth, and the teeth, were covered with a dark brown or black sordes; great difficulty of breathing came on, apparently from some obstruction at the orifice of the respiratory tube; the patient grew delirious, and expired on the following evening, being the 15th of the present month.

The patient, from the commencement of the affection to its fatal termination, had no discharge from the nostrils; did not complain, though repeatedly questioned on these points, of any pain in the joints or in the head, nor was there any affection of the absorbent glands, nor visible collections of matter in any of the external parts of the body remote from the disease—as in the groins, axillæ, &c.

The poor fellow seemed conscious that the arm was the source of the mischief, and, during the course of the affection, complained of pains shooting up and down the member; stated that he was in the habit of feeding glandered horses, and examining them after death, which he continued to do for some time (about two months) after the

receipt of the wound in the finger; expressed his firm conviction that he was labouring under that malady, which, he said, "would do for him at last."

Post-mortem Examination.—The left parotid and submaxillary glands were found indurated and adherent to the lower jaw; their substance was thickly studded with numerous small collections of pus, varying in size from a pin's head to a split pea, and around these collections the substance of the gland was highly vascular, and presented a bright-red appearance: of the two glands, the parotid was the most affected. The *alae nasi* were livid, and had almost passed into a gangrenous state. Numerous tubercular elevations, which could hardly be said to have passed into a state of ulceration, were seen on the mucous membrane of the nares. The mucous membrane lining the larynx and trachea was much injected, and an ulcer was seen on it, just below the *rima glottidis*. Several small tubercles were seen at the apices of both lungs, which Mr. C. Clark stated were precisely similar to those occurring in the lungs of horses who had died of farcy, or glanders: certainly they were different from the ordinary tubercles found in phthisical subjects. The spleen was enlarged to three or four times its natural size, probably the effects of former disease, but in its substance there were found several small collections of pus. There was also a puriform deposit within, and in the course of, the splenic vein, especially where it emerged from the substance of the organ. The mucous membrane of the stomach did not present any unnatural appearance. There was no collection of matter in the hip-joint, nor had we reason to believe that any of the other joints were effected.

The disease appeared to commence in the situation of the parotid gland, and from thence to extend to the mucous membrane of the nares and fauces.

The chief peculiarity in the foregoing case seems to be the length of time which elapsed from the receipt of the injury to the first appearance of the symptoms indicative of this fatal malady.—I am, sir,

Your obedient servant,

J. R. BRUSH,

Dresser, St. Bartholomew's Hospital.

March 29, 1840.

P.S.—Since writing the above, I have ascertained the following particulars from the wife of the man:—About

the middle of August, received the injury. Went, a week afterwards, to the North London Hospital, and had the abscess in the finger opened, and the nail removed. Continued his work for seven weeks, still making use of the injured hand, and then was admitted into St. Bartholomew's Hospital, on the 13th of October, 1839. Remained nine weeks in this institution; was then made an out-patient, which he continued to be till his re-admission, which took place on the 23d of January. From the time of his first admission into the hospital (13th of October) to the first appearance of the malady (19th of February), including a period of nearly four months, had entirely left off work; and during the time he remained an out-patient, had not been exposed to fresh contagion.

The foregoing statement, as to the time the man was entirely out of employment, was severally corroborated by his former master and the club of which he was a member, and that in consequence he was placed on their pension-list, from which he continued to receive an allowance up to the period of his death.

The nurse who attended upon John Smith, on the third or fourth day after his decease perceived a small painful tumor near the axilla. On the two following days was subject to irregular chills alternating with heat of skin, and passed restless and sleepless nights. On the Saturday evening (March 21st), the arm was very painful, and an inflammatory blush appeared. On the Sunday morning, when she first directed our attention to it, nearly the whole arm, from the axilla down to the elbow, at its inner, anterior, and posterior aspects, had become involved in an extensive phlegmonous inflammation, bearing a close resemblance to that occurring in the face of the man already detailed, but much more rapid in its progress, considerable nervous irritation being present.

There appears a strong probability that this affection is connected with that under which John Smith laboured. I am not aware, however, of any instance in which farcy or glanders (which appear to be of essentially the same nature) have been propagated from one human subject to another; and that whether, in case of absorption of the virus, the specific disease be communicated, or common phlegmonous inflammation be the result.

ON THE ETHEREAL SOLUTION OF ERGOT.

To the Editor of the Medical Gazette.

SIR,

HAVING made repeated trials of a preparation of ergot given to me by my friend Dr. G. O. Rees, I have been induced to request from him the method of its preparation, in order that I may lay it before your readers.

Although by no means a strenuous advocate for the common employment of the ergot, yet I am prepared to admit its efficacy and value in cases of protracted labour, where the presentation is natural, the pelvis of standard size, where the soft parts are dilated and fully prepared to admit the passage of the child, where uterine effort alone is wanted to complete the labour, and where there are no contraindicating circumstances forbidding its exhibition. In cases of this description, I have used the preparation, and have seen it employed by others, with complete success. I have also tested its efficacy in hæmorrhage occurring after the birth of the placenta, when the uterus has not contracted well, or where its contraction and dilatation alternated. In cases of this description, the exhibition of the ergot has been followed by a permanent contraction of the viscus, thus preventing inordinate discharge. In passive menorrhagia, when there exists no organic lesion, this form of medicine will be found of great value; the discharge is generally lessened after the exhibition of the second dose; and in no case in which I have given it, has it failed ultimately to put an end to the bleeding.

All the other preparations of ergot with which I am acquainted not unfrequently produce nausea, sickness, headache, falling of the pulse, dilatation of the pupil, &c.; but in no one instance have I seen these symptoms produced by the ethereal solution: they most probably are caused by some constituent in the drug which ether does not dissolve. I have given the solution to puerperal women in doses varying from ℥xv. to ℥xxx. dropped upon a lump of sugar, and have found that uterine action has commenced in twenty minutes or half an hour. In cases of menorrhagia, I have given ℥v. to ℥viij. three times a day, and have not had reason to persevere in its employment more than four or five days.

The advantages of this form of the drug may, I think, be stated as, first, the convenience of its exhibition; secondly, the certainty of its operation; and, thirdly, its non-production of those unpleasant and sometimes dangerous symptoms so frequently caused by the other preparations of the ergot. With regard to the method of its preparation, Dr. Rees writes to me as follows:—

“The ethereal solution, the properties of which you have so well tested, was prepared by digesting ℥iv. of the powdered ergot in f℥iv. of ether during seven days. The result was a solution of the fatty matters contained in the drug: this was poured off, evaporated to dryness, and the residue again dissolved in f℥ij. of ether. I have since tried to re-dissolve in alcohol, but the fatty matter appears to contain myricin, which resists that menstruum even at a boiling heat. The solution should be kept in a well-closed glass-stoppered bottle, to prevent evaporation. Each ounce of the preparation may be considered as equivalent to two ounces of the ergot, or ℥xv. to a half-drachm dose of the powdered drug. Should there be any objection to the administration of the ether, the practitioner has only to drop the required dose upon a piece of lump sugar, and expose it to a current of air for a few minutes, when the fluid will completely evaporate. I regret that I have not had leisure to procure the different fatty matters of the ergot in a separate form, and so subject each to trial as a medicinal agent. If this were done, there is little doubt but that a still more convenient form for exhibition might be obtained, and the peculiar action of the drug traced to its true source. It appears highly probable that the fatty matter contained in the ergot is peculiar in character: from one specimen which I examined, I obtained a fat which, when treated with strong sulphuric acid, became a fine green colour—a re-action which I am not aware has ever yet been noticed as occurring with any fatty substance either from the vegetable or animal kingdom.”

I am, sir,

Your obedient servant,

JOHN C. W. LEVER.

33, Bridge House Place, Southwark.

CONGENITAL STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of forwarding to you for publication, a portion of a communication which I have recently received from Professor Dieffenbach, of Berlin, in the hope that it may prove interesting to my professional brethren; whilst it secures, I believe, to Prof. Dieffenbach the distinction of having been the first to put in practice the operation here detailed.

It consists in the division of the musculus rectus oculi internus for the convergent variety of strabismus, the manner of performing which I shall relate as nearly as possible in Professor Dieffenbach's own words.

On the cure of congenital strabismus, by dividing the M. rectus internus oculi.

A case of division of the internal rectus for strabismus convergens, operated upon by me, was followed by a successful result. Professor Jüngken, who examined the patient, was much gratified by the success of my operation. The subject of it was a boy, seven years of age; one eye was forcibly drawn to the internal canthus, and considerable deformity was the consequence. I performed the operation in the following manner: the boy's head was supported against the breast of one assistant; a second elevated the upper eye-lid by means of a hook, whilst the lower was depressed in a similar manner, thus exposing to view a considerable segment of the bulbus oculi. With a third hook I pierced the conjunctiva in the canthus internus, and the cellular texture for a sufficient depth beneath it, and gave this to the care of a third assistant. I then, by means of an extremely fine hook, pierced the sclerotica at the internal canthus (holding the instrument in my left hand) and drew the barb outwards. Having done this I proceeded to incise the conjunctiva in this part (the internal canthus) by the side of the globe, separated it still deeper from this latter, and then divided the internal rectus, thus exposed, with a pair of fine scissors near to its insertion: with the rapidity of an electric shock, the globe darted suddenly outwards under the influence of the external rectus; it as suddenly righted itself, and at this time the axis of the eye assumed a perfectly normal

direction. The hæmorrhage during the operation was inconsiderable, but nevertheless sufficient to occasion some embarrassment in its performance. Cold lotions were afterwards applied, inflammation of the globe did not appear, and within eight days the cure was completed. I must record my acknowledgments to Dr. Böhm, for the care which he bestowed upon the patient after the operation.

Stromeyer, in his fine treatise upon "orthopædia subentanea,"* asserts the practicability of dividing the internal rectus for strabismus from the result of his researches on the dead subject, but until the present case no instance of its performance upon the living has occurred. I hope that a place in ophthalmic surgery will be awarded to it for the future.

DIEFFENBACH.

Professor Dieffenbach has repeated this operation in two more cases: both were boys, one of 11 and the other 15 years of age. In both these also a perfectly successful result was obtained. In his report of the case, it will be perceived that the side on which the operation was performed is not specified; it is most probably the right, from the fact of his holding the hook which grasped the sclerotica with his left hand. This, however, is of minor importance.

The same communication contains a recent paper by Professor Dieffenbach, upon the division of contracted muscles causing deformities of the extremities; which has been published in "Die Wochenschrift für die gesammte Heilkunde."

I should have been anxious to request a place in your esteemed journal for some of the very valuable facts comprised in this paper, but I am saved from further intrusion upon your pages, by the very comprehensive abridgment of it which has already been presented to the English medical public in one of the quarterly reviews.—I am, sir,

Your obedient servant,

JOHN LOMAS.

60, Grosvenor Street, Manchester,
March 14th, 1840.

P.S. Dr. Dieffenbach's letter is dated Jan. 18, 1840, but the date on which he performed the first of the above operations is not given.

* Beiträge zur operativen Orthopädie, oder Erfahrungen über die subcutane Durchschneidung verkürzter Muskeln und deren Schmen. Von Dr. Stromeyer, Hanover, 1838.

RECORDS OF VACCINATION.

To the Editor of the Medical Gazette.

SIR,

If you have room in your next number, and will insert the inclosed, you will oblige, sir,

Your humble servant,
E. LEESE.

Baker Street, April 1st, 1840.

This appears to be an age for disbelief and doubting, and by some remarks in a late number of the 'London Medical Gazette,' Mr. Estlin, of Bristol, has doubts as to the data upon which the late report of the "National Vaccine Establishment" to government, with regard to the pedigree and unbroken line of vaccine virus from the days of Dr. Jenner, is founded. He doubts also some statements made by me in another publication: the reply I make, so far as I am concerned, is, come and see, or depute a friend to do so. I will then lay before him a list of the numerous practitioners whom I have supplied with virus, and figures denoting the child from whom it was taken in each instance. He may then peer through fourteen folio volumes, and see the names and residences of every one of the individuals who have been vaccinated at the station entrusted to my management: so plain, yet comprehensive, is the detail rendered by the help of a few figures, in the ruled and printed books furnished to me for registration, he may readily trace the catenation, retrospectively, from the end of the last to number one in the first, and convince himself how groundless are his doubtings and surmises. I agree with him, that these registers, with the various remarks they contain, through the lapse of forty years, are of very high importance to the practice of vaccination. If the register kept by me do not remove his doubts, let him proceed to the other government stations: I know that my worthy and respected friend, Mr. Gilham, has an unsevered chain of pedigree, including upwards of 89,600 names, without a link broken.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

PHYSICAL CONDITION OF THE WORKING CLASSES.

MR. CARLYLE remarks, in his instructive essay on Chartism, that among the various topics which occupy the representatives of the nation, the "condition-of-England question" is omitted. We are not to understand, indeed, that the reform of chapters and corporations, or discussions on "what the Swede intends, and what the French," are wholly alien to the subject, but that they do not go to the root of the matter. Hence we were glad to see, that, at the beginning of the session, a philanthropist moved for a committee to inquire into the most essential part of the subject; and it affords us additional pleasure to find that he has embodied his views in the tangible shape of a pamphlet.*

One is inclined to regret, indeed, that among the six hundred and fifty-eight members of the House of Commons, there is not room for half-a-dozen sensible physicians, who might act as interpreters between rich and poor, and inform their fellow deputies of the real state of the working classes. In two nights they would set forth evils and their remedies with more force of persuasion than a select committee could attain to in three months. But, for the present, destiny has ordered it otherwise; and, as we cannot have Dr. Alison in the House, we must be content with the benevolent speech of Mr. Slaney.

After a short sketch of the deep-rooted

* State of the Poorer Classes in Great Towns: Substance of a Speech in the House of Commons, Feb. 4, 1840, on moving for a Committee to consider the causes of discontent. By Robert A. Slaney, Esq. M.P. With Notes and References. London, 1840.

uneasiness of the lower classes, as shown in the Luddite riots of 1812, the Manchester meeting of 1819, and the rising of Brandreth and his associates in 1821, Mr. Slaney comes to the grand topic of the day among thinking persons—*chartism*, and all that this weighty word implies. It may be asked, he says, “to what causes do you attribute the growth and increase of discontent among these industrious classes?” To this Mr. Slaney answers, “that we are able to show very great changes in the social condition and in the numbers of the working classes, in populous districts, within the last century.”

These changes have been overlooked or neglected by successive administrations, so that when the rich and luxurious at last awaken from their sybaritic dreams, they are affrighted at the angry discontent around them, and call for bayonets and penal laws, instead of moral training and physical comforts for the poor. One of these changes is the alteration in the ratio of the manufacturing to the agricultural population. “In 1790, the number of manufacturers and workmen living in towns was, to the labourers in the country districts, as one to two. In 1840, the proportions have become exactly reversed, and the numbers of the former are to the latter class as two to one. In forty years from 1800, agricultural labourers have increased from 40 to 45 per cent.; whilst workmen in towns and manufacturing districts have augmented 120 per cent., and in *great towns* much more.” (Slaney, p. 11.)

In the period between 1800 and 1831, Leeds increased 99 per cent. in population; Liverpool, 100; Glasgow, 108; and Manchester, 109. In the West Riding of Yorkshire, the proportion of manufacturers, miners, and town workmen, to labourers in husbandry, is 3 to 1; in Lancashire, 10 to 1; and in Middlesex, 12 to 1.

One of the inevitable results of a town population is the crowded state of its inhabitants; and among the manufacturing classes, the employment of women and children in factories and workshops is unfavourable to physical and moral health, and tears up the charities of life from the roots. Another consequence is, that the poorer classes learn to analyze their own state, and the remedies which might be applied to it; and men who, in the language of Sir William Jones, “know their rights, and knowing dare maintain,” are often uncomfortable neighbours during that embryo state in which their rights have not yet assumed the shape of law.

In order to disturb the frame of society, it is not requisite that the condition of these men should be worse than that of their forefathers, but simply that it should be worse than what they clearly see to be attainable under a happier state of things. Thus, in the great outbreak of France in 1789, the state of the nation was not worse than it had been previously; not worse than that of many other European states; but most wretched, when compared with the wants and capabilities of a nation through which knowledge had been long and widely diffused. This the lords of hill and valley could not, and would not see; so they were swept away like noxious exhalations before a hurricane, purifying and destroying in its career! Now, the six members whom we wish to see in the House, would illustrate this simple matter better than the choicest of select committees; those whose daily occupation had brought them into familiar intercourse with the artisans of London and Birmingham, might explain to gentlemen of 8000*l.* a-year that we are no longer in the sixteenth century, and cannot be governed by its rules. Mr. Carlyle justly observes, that the rights of man vary with the time, and that the Highland woman, who, amid her tears,

said to her husband, at the foot of the gallows, "Go up, Donald, the Laird bids ye," thought much of the rights of lairds, and little of those of men. But what if it should turn out, on examination, that, in spite of the progressive wealth of England, large classes are untouched by the golden shower, and may be retroceding in the general advancement? In a great city, we have not merely the startling contrast between the employer and the workman :

"Here, while the courtier glitters in brocade,
There the pale artist plies the sickly trade;"

but, even among those who minister to the wants of society, the difference in condition is surprising. We must not trust to those statistics which shew the increase of consumption in articles of luxury, but we must look into the actual condition of the less favoured classes, and not be content with judging in the lump. "The richer and middle classes have much increased their comforts and conveniences, and we may hope and believe that the situation of a portion of the working classes (whom we will call the *skilled* labourers) has improved also. With respect, however, to a very large proportion, we shall, we fear, on inquiry, find that their condition not only has not improved, as it should have done, in proportion to that of the richer classes, but that in many respects it is much worse than it was before."—(Slaney, p. 14.)

One of the first points which will shock the philanthropist who enters upon this subject with the attention which it deserves, is the state of the dwelling-places of the working classes. Thus, Nottingham contains about 11,000 houses; and of these, from seven to eight thousand are built back to back. When the town was first visited by cholera, many rows of houses were found to be placed upon drains, which were covered only by the boards of the sitting-room floors.

In Liverpool, there are 7862 *inhabited cellars*, containing 39,300 persons; being full a fifth of the working classes. At Manchester, when a board of health was established, in expectation of the cholera, of 687 streets inspected, it was found that 248 were unpaved, and 53 but partially paved; that there were 352 which contained heaps of refuse, stagnant pools, &c.; and that of 6951 houses inspected, 2221 had no privies. In the same town, nearly 12 per cent. of the working population live in cellars. In Bury, with a population of 20,000, it was found that

In 773 houses, they slept 3 to 4 in a bed.

In 207 " " 4 to 5 "

In 78 " " 5 to 6 "

These last data are taken by Mr. Slaney from the Report of the Manchester Statistical Society on the State of the Working Classes, and are enough to rouse the most apathetic. Facts, always generically the same, though sometimes differing in species, are stated of Newcastle, Leeds, Glasgow, and London.

"In some parts of Bethnal Green and Spitalfields," says Mr. Hickson, "inhabited by weavers, every house ought long ago to have been condemned and razed to the ground. Ruinous buildings, streets without sewers, overflowing privies and cesspools, and open ditches filled with a black putrifying mass of corruption, infecting the air for miles around, render the district the abode of disease and death."

The obvious remedy, as recommended by Mr. Hickson, and approved by Mr. Slaney, is a good Building Act, applicable to every town in the United Kingdom. The good old maxim, *sic tuo utere, ut alienum non lædas*, is here especially apposite. It is enforced in London, with respect to party-walls and parapet roofs; but is equally applicable to drainage, paving, and the width of streets. To allow a landlord to build any houses that he may find marketable

among the poor and ignorant, is, in effect, to allow him to set man-traps.

The establishment of public walks in the vicinity of densely peopled towns is so obvious and necessary an improvement, that it requires but to be mentioned, without comment. It is remarkable that Mr. Slaney says that he shall not be deterred by the fear of ridicule from again urging its necessity. To cast ridicule on a project combining the clearest utility and the finest taste, seems strange, indeed; but, as Goldsmith tells of an author who could draw up an answer to any book at twenty-four hours' warning, so there are some persons who would write you an epigram against a clean shirt or a tooth-brush. Or, perhaps, the true reason is, that certain beings have an innate aversion to any improvement, lest, if beneficial changes went too far, *they*, too, should be swept away.

Another great point is to enable the working classes to ensure themselves against the fluctuation of employment and wages by benefit societies. The ordinary clubs under this name are confined to cases of illness or death; and something is wanted to afford a stipend when men are out of work, and thus make the years of plenty provide for the time of famine. The 4 & 5 Will. iv. c. 40, gives legal facilities for this purpose; but its provisions are not yet much known or acted upon. Mr. Slaney benevolently proposes that some bonus, or other inducement to the formation of such societies, should be held out by government or private persons.

Among the other subjects touched upon by Mr. Slaney in his good-humoured speech, are the increase in the committals of criminals and the consumption of spirits, and the necessity of providing for the growing wants of the people by an augmentation in the number of churches and schools.

A select committee was appointed,

not with the wide range of inquiry originally proposed by Mr. Slaney, but "to consider circumstances affecting the health of the inhabitants of large towns and populous districts, with a view to improved sanatory regulations for their benefit."

We wish every possible success to its labours.

CLINICAL LECTURES,

Delivered at St. Vincent's Hospital,

By J. M. FERRALL, Esq., M.R.I.A.,

First Medical Adviser to the Hospital.

Periostitis—comparative value of the different modes of treatment—That by incision—case—constitutional disturbance—cure in 28 days. Treatment by Mercury—case—cure in 37 days. Treatment by Hydriodate of Potass—cure in 13 days. Comparison of the rapidity and safety of the three plans—cases with and without suppuration—the Hydriodate available in both—utility of Sarsaparilla.

GENTLEMEN,—We have just now had three cases of periostitis under observation at the same time, and I availed myself of the opportunity of testing, for your instruction, the comparative merits of the several modes of treatment recommended for the cure of this disease. These are, the treatment by *free incision*—by *mercury*—and by *hydriodate of Potass*. Certain circumstances in the origin and stage of this disease will often influence our decision as to the particular course to be pursued, but the cases under your notice were tolerably well calculated to display the effects of remedies, and their results, being as nearly as possible analogous forms of the complaint. The form of periostitis to which I allude, may be termed *circumscribed*, in contradistinction to the *diffuse*, which engages a larger extent of the membrane, and ends speedily in necrosis of the subjacent bone. I mentioned to you in a former lecture, my objection to the terms *acute* and *chronic* in affections of the osseous system and its coverings; length of time is no measure of chronicity in inflammation of these structures. A marked practical difference will be observed, when you study the periostitis which invades the whole or greater portion of the coverings of a long bone, and compare it with that which occupies a more limited space, however severe the sufferings of the individual in the latter case.

The pupils of this hospital have witnessed the several plans of treatment to

which I refer, adopted in individual cases from time to time, but more frequently that by the hydriodate of potass, on which I have the greatest reliance. But as pupils do not always continue to observe the same practice for a lengthened period, the present occasion is favourable for enabling you to form an opinion, and decide upon that which you will in future employ.

REPORTED BY MR. WILKINSON.

Periostitis treated by incision—cure in 28 days.

Mary Magrane, aged 40, was admitted into Joseph's ward, on the 2d December, labouring under the following symptoms: excruciating pain in both tibiæ about their middle, the pain extending above and below for a considerable distance. It was greatly aggravated by the depending position, and so intense at night that she positively declared she had not slept for three weeks; her appearance shows great exhaustion; her appetite is gone; her tongue pale and slightly coated; pulse 96; bowels irregular; renal secretion scanty, and depositing the lithates.

Dec. 3d.—The state of the limbs is as follows: there is a visible swelling occupying the seat of pain in both tibiæ, and fading gradually off to the distance of an inch and a half at either end from its central prominence; the left is not discoloured; it has a firm feel, with the sensation as if the cutaneous vessels were enlarged and rolled under the finger; there is very slight œdema; the sensibility of the part is very great when pressed: the right exhibits a swelling of the same dimensions; it has a dusky red colour, and in its centre there is distinct fluctuation surrounded by a firm border.

She states that she never had any specific disease, her husband being a remarkably well-conducted person. She has never had rheumatism, nor used mercury in any way, of which she was aware: the complaint began in the right leg about four months ago, by pain, which was only felt at night, but did not prevent sleep; this very gradually increased, and she then perceived the part to be swelled. The left leg became affected about six weeks ago, and the pain was in the beginning nearly as severe as at present; she remarked that from the time the left shin bone was attacked, the pain in the right became suddenly worse, and soon acquired its present red colour. Some aperient medicine is directed, and a broad poultice laid on the parts, which are to be kept in an elevated position.

Dec. 4th.—She passed a wretched night; she thought herself much easier for an hour after the limbs were raised, but the position soon ceased to afford relief. An incision two inches long was made through the fluctuating swelling on the right tibiæ,

and carried down to the bone: about a drachm of pus of a pale brown colour escaped; the bone felt bare to a probe introduced through the opening.

A similar incision was made through the swelling on the left tibia; the periosteum was found adherent as usual to this bone; the hæmorrhage from both was free, but not copious; a bread poultice was laid on each after a short ablution with warm water: the elevated position was resumed.

Dec. 5th.—She states that the smarting of the incision did not last long; the pain is quite relieved as long as the limbs are kept raised, but she cannot bear the depending position; her sleep was refreshing, and lasted several hours. The surfaces of the incised parts exhibit a lymph covering, that of the right discharges a brownish pus of disagreeable odour; appetite better; she has some thirst; pulse 84.

Mist. efferves. 3tiis horis.

Dec. 7th.—She does not feel so well to-day; her thirst continues, and she did not rest well last night, although free from pain in the limbs; pulse 90; skin hot. The urine, which had become more copious and clear, is now again scanty and red, but without sediment. The left limb looks favourably, and healthy pus appears on the poultice: the right exhibits more tumefaction and redness.

Six leeches to be applied in the neighbourhood of the incision; fomentation and poultice: the effervescing mixture to be continued.

R Massæ pilul. Hydrarg. grana tria;
Pulv. Jacobi, grana duo. M. ft. pilula.
hora somni sumenda. Mist. Cathart.
prim. mane.

Dec. 9th.—The feverish condition has nearly subsided; she slept soundly last night, and enjoyed her breakfast this morning; tongue clean; pulse 76; urine natural. The left wound is granulating, and less in size. The right is throwing off a sloughy pellicle, and healthy pus exudes from the subjacent parts; she is ordered nourishing diet.

December 14th.—Both wounds present a healthy granulating appearance; the granulations in the right are closing in over the bone, and the probe no longer reaches it: the appearance of the granulations here is somewhat different from the other, they are rather larger, but their colour is scarcely less florid; healthy pus escapes from both; there is no return of pain.

December 20th.—The left tibia now healing rapidly: the right is filling up, but the granulations still want the appearance of health; she continues to improve in strength, and feels no soreness except when

standing erect: the parts are dressed with soap plaster.

December 26th.—The wound on left tibia is healed. That on the right has assumed a perfectly healthy aspect within the last two days; it is filled up, and begins to cicatrise at the edges.

January 2nd.—The parts are quite healed; she can now walk with ease; the soap plaster and a light roller appearing to give sufficient support to the vessels of the limbs.

You perceive that some slight degree of constitutional disturbance followed the incision in this case; and at that period, (the third day after the operation) we apprehended our patient was about to be visited by erysipelas, for the edges of the wound on the right tibia were tumid and tender, and the integuments around had an inflamed appearance. The employment of a mild mercurial aperient, conjoined with James's powder, and followed by the house mixture, seemed to check this feverish state: the irritation was probably connected with the sloughing of a small portion of the exposed periosteum, which came away a few days afterwards. If any part of the surface of the bone was parted with, it is probable it was dissolved or absorbed, for it was not observed at any subsequent period, in the discharge. You are aware that the question of the mode in which dead bone is disposed of is yet unsettled, and therefore we cannot speak positively on this point. The granulations, you must have remarked, were larger on this leg than the other until the 20th day, when a perfectly healthy action was established, and the healing was soon accomplished; this was completed on the 28th day after the incisions were practised, and then for the first time she could bear to throw the weight of the body on the limbs, although every assistance was afforded by the support of straps of soap plaster and bandage.

The next case exhibits the influence of mercury on this disease.

REPORTED BY DR. DROUGHT DICKSON.

Periostitis treated by Leeching, Blisters, and Mercury—Cure in thirty-seven days.

Bridget Reddy was admitted into Joseph's Ward on the 22d November.

This woman was about 28 years of age, married, of regular habits, and free from any specific disease. There was nothing to account satisfactorily for the occurrence of severe pain in both shin-bones about six weeks before she applied to the hospital. The pain was slight at first, but became more intense afterwards, and, being worse at night, had altogether deprived her of rest.

Both tibiae exhibited the characteristic

swellings of periostitis; circumscribed tumors, slightly pitting on pressure, exquisitely tender to the touch, and marked by a faint dusky redness. That on the left tibia was lower down than the right; the blush was scarcely perceptible, except that when the finger was applied, a spot whiter than the remainder was visible for a moment afterwards.

Six leeches were directed to be applied to each tibia, followed by a poultice; the foot to be raised, a mild cathartic draught, and afterwards the following pills:—

℞ Hydrarg. Submuriat. gr. xij.; Extract. Opii, gr. ij. M. ft. Pilulæ sex, una ter in die sumenda.

24th.—She slept for two hours after the application of the leeches, but the pain returned before morning.

Hirudines duodecem, pilulæ ut antea.

29th.—The pain has been occasionally very severe, but is now much better; the mouth is now sore; bowels frequently moved, with some griping and tenesmus. The pills were ordered to be omitted, and a draught composed of rhubarb, magnesia, and tincture of opium, given.

December 2d.—The pain is much lessened, but the tenderness on pressure remains. The œdema and slight redness are entirely removed; the bulk of the swelling is decreased; the gums are more swollen, and salivation is increasing. A gargle is ordered. The bowels are moved two or three times daily, but without pain.

Hirudines sex tibiis.

6th.—The pain and tenderness on pressure are altogether removed; her sleep is disturbed only by the soreness of her mouth; patches of ulceration are visible on the inside of the cheeks.

A lotion of nitrate of silver to be applied to the inside of the cheeks.

9th.—Having left bed for two hours yesterday, she was disappointed on finding that the depending position of the limbs reproduced the pain in some degree. The swelling has not undergone any further change; it is slightly painful on pressure; the cheeks are quite healed, but salivation continues in a moderate degree.

Ordered to remain in bed, and apply a blister for four hours to each tibia; the part to be dressed with Ung. Hydrarg.

16th.—The blister is healed; there is some diminution of the swelling, especially of its extent: she is quite free from pain as long as she remains in bed, but a few hours in the erect posture produce a feeling of weight and distension. The gums are still tender, and prevent her tak-

ing solid food. Six leeches to be applied as before.

24th.—The last leeching enabled her to use the limb more freely, but she cannot stand for any length of time without feeling a return of the sense of bursting in the parts. Her health is now quite good, and she can take food in sufficient quantity. In order to support the superficial vessels, the swellings are covered with straps of soap plaster, and a light roller is applied from the toes upwards.

30th.—She can now stand and walk without inconvenience: she has been improving since the parts were bandaged, but only now feels her accustomed power of using the limbs.

From this period until she left the hospital (early in January) she was quite free from pain or inconvenience: the swelling was lessened, but a hard unyielding elevation, about an inch and a half in its long-diameter, remained.

This case, gentlemen, as well as that of Magrane, exemplifies the principle which obtains in all inflammations of external parts—namely, the necessity for affording mechanical support to the weakened vessels, when the acute stage has passed away. The utility of the bandage and straps of soap plaster was observed immediately on their application. The patient was then able to support the weight of the body on the limbs, and lost that distressing sensation of bursting which you have so often heard them describe. The effect of local blood-letting was merely temporary, and unlike that which follows this measure in inflammation of other structures; nor is there any reason to suppose that leeching, pushed as a remedy to any extent, is capable of curing the disease when unaided by other means: on the contrary, the cases in which it has been tried have disappointed those who made the experiment.

We succeeded in curing this patient by mercury; but we cannot help admitting that considerable inconvenience, and some degree of risk, attended the process. The medicine was withdrawn the moment the gums became slightly touched; and yet you remarked to what an extent the salivation afterwards proceeded. This is always an untoward event, for the gums are sometimes permanently altered in appearance from this cause; and this, at a period when mercury is less extensively used than in former times, is always a subject of regret, and often of complaint, by the individual. Now, whatever caution is employed in the use of this mineral, and however systematically the course is conducted, this excessive salivation will occasionally occur, for we sometimes see ulceration of the gums and cheeks where the

mildest preparations have been used, and in the smallest doses. The diarrhoea was also a source of annoyance; and, in bad constitutions, mercurial diarrhoea is sometimes very obstinate. It generally yields to the remedy you employ, but is in some instances disposed to return, and then will, perhaps, resist the medicine which succeeded before. The case of Ward, the man who was treated for acute arthritis confined to the knee-joint, was cured by mercury, but suffered for two or three months from constantly recurring diarrhoea. He went out of the hospital quite well, but considerably reduced by the illness. I suspect that in some of those cases of protracted diarrhoea, from the use of mercury, and of the mercurial dysentery (which is, perhaps, the more frequent occurrence of the two), that a state of the mucous surfaces exists, analogous to that which we discover on the inside of the cheeks, and would be as easily controlled if we could apply our remedies to the abrasions.

The almost specific powers of the hydriodate of potass, in periostitis, are exemplified in the next case, which is interesting in more than one point of view.

REPORTED BY MR. W. M'MAHONE.

Periostitis, with Suppuration, treated by Hydriodate of Potass—Cure in thirteen days.

Anthony Hussey, æt. 33, a carpenter, was rendered incapable of working at his trade for five months, by pain and swellings on both tibiae. Although a strong man, he felt quite exhausted by loss of rest, for the pain was most agonizing at night, and entirely deprived him of sleep of more than half an hour's continuance. His sleep was sure to be broken by intense pain in the tibiae, and he could procure partial relief only by walking about the room until he became cool.

In this state of suffering, Hussey was admitted into Patrick's Ward on the 5th December, and the parts, on examination, presented the following appearance:—

A circumscribed swelling existed, about three inches below the head of each tibia: that of the right leg was firm, and nearly unyielding to pressure; it occupied about two inches of the surface of the bone. A dusky blush was observed in the integuments, and a very slight œdematous pitting to the finger. His suffering was greatly increased by the examination. The left tibia was more inflamed in appearance; the swelling was about the same size, but in its centre, where the skin was reddest, a distinct fluctuation, surrounded by a firm border, was observed.

This man attributed his complaint to rheumatism from exposure to rain. He had used mercury, but not for ten or twelve years.

In order to contrast the results with the treatment by incision, the parts were covered simply with a dossil of lint moistened in tepid water, and he was put on the hydriodate of potass, in doses of eight grains three times a day.

The first night was passed, as usual, in torture; the second he thought better.

Dec. 7th.—Hydriod. kali, gr. xij. ter indie.

8th.—No pain last night; slept much better.

9th.—Slept soundly last night, and feels refreshed. The inflammatory blush of the skin is much fainter, and the cedema nearly gone. The fluctuation in the left tibia persists. Ordered hydriod. kali, gr. xvj. ter indie.

15th.—Hussey is in great spirits to-day, and cannot be kept in bed. He is entirely free from pain night and day. The fluctuation in the left tibia is nearly gone, the swelling is diminished, and the colour of the parts is a pale brown. With a view to further reduction of the thickening of the inflamed membrane, the hydriodate was increased to 20 grains three times a day.

18th.—No trace of fluctuation; the swellings are very much lessened, and are now hard and quite sensible to pressure. He begs to be allowed to return home.

You all observed what a remarkable improvement took place in Hussey's appearance when he began to sleep at night. In fact, the poor fellow was worn out by suffering and loss of rest, and would have cheerfully submitted to any operation likely to procure relief. I was willing, however, to give a trial to the hydriodate before resorting to incision, although our hope of succeeding was lessened by the discovery of distinct fluctuation in the left tibia, especially as it was encircled by a firm border, which left no doubt of the nature of the sensation conveyed to the fingers. There was another circumstance in this case which diminished the probability of procuring absorption by internal remedies. This man had been an out-patient two years before on account of an ulcer on the left ulna near the olecranon. The ulna was exposed and rough at this point, and the sore healed only after the exfoliation of a small plate of bone. This complaint he distinctly described, at the time, as originating in a hard painful swelling on the bone, which, after some time "broke," and discharged a "yellow stuff." There could be no doubt that all this was circumscribed periostitis of the ulna ending in suppuration; and I think we may fairly presume that the swelling in the tibia would have followed the same course. I do not wish to convey to you that he might not ultimately have got well of the latter disease, but compare a tedious suppuration with exfoliation from

a bone in the lower extremity, and which would, in all probability, have deprived him of all means of earning for months: compare this with the rapid amendment which occurred under the use of the hydriodate of potass, and which really occupied only thirteen days altogether, for the last seven or eight of which he considered himself well, being quite free from pain.

The local treatment in this case was intentionally simple, in order that we might be able to judge fairly of the powers of this salt. Leeching, which in Reddy's case was combined with the internal use of mercury, was here omitted, and you perceive our patient was relieved in a much shorter time.

In comparing the results of different modes of treatment in this painful disease, you have to consider—1st, by which is the pain most speedily relieved,—2ndly, which restores the power of using the limb soonest to the patient,—and, 3rdly, which plan of treatment is attended by least danger and inconvenience.

Now, if the three cases at present under review were the only instances in which I had made the trial, I could not allow you to form any judgment from them alone. But as the results correspond very closely with those observed by myself in many others, and even in this hospital, by such of you as have been attending its practice for more than the present session, I may safely permit you to regulate your practice by their events.

As regards the immediate relief of pain, there can be no doubt that incision, where it succeeds, has greatly the advantage of the mercurial treatment. The merit of having insisted on this practice in periostitis is due to Sir Philip Crampton, whose excellent practical paper on this subject you will find in the first volume of the Dublin Hospital Reports. I say, *where it succeeds*, for some of the cases in the essay to which I allude are indicative of its uncertainty, except when the surgeon has an opportunity of employing it in the early stage. In one of his cases, in which incision was followed by immediate relief to the part incised, the disease attacked the periosteum immediately below the point of incision, within a week from the first operation. A new incision was now made to relieve the latest point of attack, and relief followed as before; but before this last wound was healed, an attack of pain, which was only relieved by a nightly dose of opium, occurred in the seat of the original incision. In another of his cases, (that reported by the late Professor Todd) but which was of longer duration, the incision was followed by partial relief, and the patient, a lady, left town, suffering severe pain occasionally afterwards in the country.

The hydriodate of potass is generally

capable of controlling the morbid action, and relieving pain in a shorter time than I was prepared to expect. The fifth or sixth dose will, in the majority of instances, enable the patient to sleep; and I have known many instances where the third or fourth dose has produced this effect. I have notes of cases amongst our out-patients, who slept the first night, having taken during the morning and day four doses of the salt, and I have never failed in demonstrating to you, by the usual tests, the presence of the medicine in the urine passed the following morning. The purity of the hydriodate, you are aware, is ascertained, before any new parcel is used by the apothecary. There is very little difference, therefore, in the period at which the pain may be relieved; and when you consider that the iodine treatment avoids a painful, though brief operation, and is not followed by an open sore, I think you would prefer, in your own instance, giving it a previous trial.

The second ground of preference, namely, the earlier period at which the patient can resume his occupation, is clearly on the side of the iodine, for the case treated by mercury occupied 37 days, that by incision 28 days, and that by the hydriodate of potass 13 days. In the two latter cases, matter had formed beneath the periosteum, and this circumstance, while it accounts for healing after incision being a few days slower than in the first case of Sir Philip Crampton, gives an additional value to the iodine, for it displays its power over the disease, when even advanced to suppuration, and its capability of curing it in a shorter period.

With respect to the comparative safety of the three modes, you will remember that some degree of constitutional disturbance followed the incision, and that ulceration of the cheeks and diarrhoea succeeded to the mercurial plan. Amongst the consequences of the use of hydriodate of potass, none have occurred under my observation at so early a period as to oblige us to desist; and if gastric irritation should occur, which never happened in any instance where it was used for periostitis, it is very easily removed. The more remote effects of the hydriodate, of which I shall speak hereafter, have nothing to do with our present inquiry.

As regards the origin of the periostitis, I do not think it exerts much influence, or opposes any special obstacle, to the success of this medicine. The form which Dr. Macleod, in his Lectures on Rheumatism, designates periosteal rheumatism, appears to yield with facility to its operation. You must not, of course, overlook the general condition of the patient, or the existence of fever, if it should exist, in the latter case.

There is another medicine of great power in subacute and chronic periostitis: this is sarsaparilla. I think Sir Philip Crampton speaks too feebly of its powers in this complaint, and indeed he appears to limit its exhibition to those cases in which periostitis is connected with that cachectic state produced by protracted courses of mercury. In these, he says, it may be given with considerable advantage; but he does not say that it is capable of curing the disease alone. I have given it repeatedly with the effect of removing the pain in a few days, since it was suggested by Sir B. Brodie, a few years ago, in the case of a gentleman who consulted him when attacked in London by this painful malady. In this case there was no mercurial cachexia to give rise to the disease, and here, as well as in several other instances, where I did not expect to have an opportunity of superintending the action of iodine, sarsaparilla has completely succeeded in removing the symptoms.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

PATHOLOGICAL DEPARTMENT.

April 7, 1840.

DR. CLENDINNING in the Chair.

Dislocation of the Elbow Joint, followed by Anchylosis of the Ulna to the Humerus, with ligamentous union of the Radius.

MR. LANGSTAFF exhibited a preparation of dislocation of the elbow joint. The ulna and the radius have been thrown to the outside; so that the articulating surface in the lower head of the humerus for receiving the ulna, and the cavities for the reception of the coronoid and olecranon processes, are exposed to view, while the ulna is fixed in a mass, by bony union, to the rounded smooth surface for the articulation of the radius. Attached to the external condyle is a fibro-cartilaginous growth, in which a portion of bone is imbedded, forming a buttress for the head of the radius. Between this part and the cup-like depression on the head of the radius, there is a firm ligament, of a triangular shape, which bears a resemblance to the round ligament of the hip-joint, and must have permitted rotatory motion. The lesser sigmoid cavity, for the lodgment of the radius upon the ulna can still be observed, and is not much changed in appearance. It is perceived, from the preparation, that the patient retained the rotatory motions of the radius; but it is also observed, that his arm was united, in the extended position, so as to have prevented flexion altogether.

Mr. Liston made some observations in regard to the period when it might be con-

sidered hopeless to reduce a dislocation of the elbow joint, and mentioned three weeks as the latest time; remarking, that he had seen a band of surgeons foiled in the attempt when only a fortnight had elapsed. He said, that patients who had suffered dislocation of this joint, if due means were employed, might often recover the motions of the limb to a very striking degree.

Two preparations, exhibiting a multilocular appearance of the descending colon, with caecal cavities, containing concretions of cholesterine, covered with calcareous deposit.

Mr. E. Wilson, in the former meeting of the pathological department, had referred to the above preparations, as may be seen by our report in the last number of the *GAZETTE*. They exhibit different views of a part of the colon, which presents some unusual appearances. The interior of the bowel is subdivided by numerous septa, stretching nearly quite across; and various pouches, or diverticula, capable of receiving the point of the little finger, project from the gut. In each of these diverticula, concretions, varying in dimensions, but commonly of a size to fill the pouches in which they are contained, are lodged. Upon examining these chemically, they were found to consist of 80 parts cholesterine; about 20 parts of carbonate of lime; and 2 of animal residue.

Extensive Ossification of the Pericardium.

Mr. E. Wilson next placed on the table a heart, in which the pericardium surrounding it was converted into a thin case of bone. The calcareous deposit was included in the fibrous tissue of the membrane; and reached to the points of reflection of the serous membrane upon the heart, being arrested there. It was nearly of an equal thickness in all its extent; and it admitted of being cut with strong scissors. Adhesions of a firm nature were contracted between the pericardium and the surface of the heart. The cavities of the heart presented no unusual appearance; and the aorta, with its valves, seemed healthy. The tendinous part of the diaphragm, where the pericardium is connected with it, was converted into a firm cake by the osseous deposit, the concretion stopping suddenly at the part where the muscular fibres commence. In a communication sent to Mr. Wilson with the preparation, it was stated that the patient was sixty-five years of age, and had been ailing for twenty-five years. It was never, however, suspected, during life, that there was any derangement of the circulating system.

Ossification of a portion of the heart.

Mr. Shaw exhibited a preparation of

ossification of a considerable portion of the walls of the left ventricle of the heart. In this specimen, all the tissues that form the parietes were involved, inasmuch as the bony deposit presented both internally and externally, and composed the substance of the heart at this part. The coronary arteries were ossified, and had their coats much thickened. The valves of the aorta had warty excrescences upon them; and there were particles of ossific deposit on the inner surface of the aorta itself. The right cavities of the heart presented a healthy appearance. About eight ounces of serum were effused in the pericardium. The patient had been subject, for three years before his death, to attacks of dyspnoea, attended with violent palpitation of the heart, induced by exercise, or any cause of excitement.

A discussion arose as to the primary seat of such ossific deposits; in the course of which, Dr. Clendinning called to mind a specimen exhibited by Andral to his class, in which about a foot square had been converted into bone. Dr. H. Lec had seen a heart, in the possession of the late Mr. A. Burns, of Glasgow, converted entirely into bone. On its being questioned whether the muscular tissue was ever the seat of ossific deposit, reference was made by Dr. Clendinning and Mr. Arnott to a skeleton which Mr. Abernethy was wont to show to his class, where deposits of the kind alluded to were formed in the course of the different muscles, and especially along the back. These were caused, as Mr. Abernethy explained, by the infliction of blows, or other injuries on the parts,* when the patient was alive.

Large tumor in the brain.

Mr. Bainbridge exhibited a tumor of unusual dimensions, found in the posterior part of the cerebrum of a child, nine years of age. It was accompanied with a drawing by Mr. Sylvester. The tumor was composed of a dense substance, firm, and elastic, presenting in some degree the appearance of medullary sarcoma, as frequently seen when affecting the testis. It was marked on the face of the section that had been made to expose its interior structure, with areolæ of fibres, which supported a softer and yellower substance, that approached to the appearance of scrofulous tubercle. The whole tumor, however, was denser than those tubercles are usually found to be; it was easily separable from the part of the brain on which it

* Were these not mere specimens of exostosis? Such growths commonly follow blows, in patients subject to that disease. See a skeleton, in which nearly all the joints are soldered together, or immovably locked by exostosis, in the College of Surgeons' Museum. See also Phil. Trans. vol. xli. p. 10.—ED. GAZ.

was imbedded, owing to the brain around it being softer in texture than natural. It was nearly spherical in shape, the diameter being $3\frac{1}{2}$ inches; it was lodged in the posterior part of the left hemisphere, reaching from the upper surface down to the corpora quadrigemina; which bodies were found pulpy, and of a deeper red colour than is natural. The dura mater adhered so closely to the upper surface of the tumor that it was necessary to dissect it off carefully with the scalpel to expose the tumor. Three ounces of serum were found within the ventricles; otherwise, the brain appeared healthy, as were all the other viscera of the body. The child was observed by her mother, to be ill, more or less, for two years before her death; but no decided symptoms of affection of the head manifested themselves till thirteen weeks before she died. The first indications of illness were merely a heaviness or languor, that made her indisposed to join her companions in play, and would induce her to lie down, until the time for going to school arrived, when she evinced great alacrity, and was superior in her attainments to the rest of the scholars. She occasionally complained of headache, and waked up at night with pain in the head; she also vomited frequently. Thirteen weeks before death, she was seized with convulsions, and after the first fit it was found that the left side was paralyzed, and there was a squint in the left eye. She had two other fits, within three days of each other, and these consisted principally in spasms affecting the left side.

Immediately subsequent to the occurrence of these fits, she fell into a comatose condition, in which she continued for a week. At the expiration of this time she awoke, and, in her natural tone, begged to have a pear out of her bag; which it was remembered had been put into her bag previous to her becoming comatose. It was now discovered that she had lost the power of vision in her left eye. She fell again, at different times, into a comatose condition; without, however, being convulsed. Gradually she became blind in both her eyes. During the intervals, it was observed that her mental faculties remained unaffected, and her memory was especially acute. She complained particularly of pain in her head and in her left arm. An hour or so before death, she was again seized with convulsions, which lasted till she died.

Some hesitation was expressed by the members, after inspecting the tumor, as to affirming what was its precise nature—whether fibrous or medullary; but, as far as we could judge of the prevailing opinion, it leaned towards it being the medullary sarcoma.

Mr. Arnott drew attention to the remarkable extent to which the brain sometimes admits of being compressed: whether by a solid tumor, as in the present instance, or by serous effusion, if that compression take place in a gradual and slow manner. He gave two instances that came under his observation, that afforded striking illustrations of this fact.

Large Osseous Tumor of the Uterus, which nearly filled the true pelvis, and occupied part of the left iliac region.

Mr. Arnott was induced to exhibit to the meeting a preparation which he had formerly shewn to the Society, before the pathological meetings were established, as he had now, through the kindness of Professor Daniel, the opportunity of describing its chemical composition. In a former report of the proceedings of the Society, we described the appearance and history of this tumor. Mr. Arnott briefly mentioned again that it was taken from a lady, 72 years of age, who had fallen when walking in the streets, and had suffered rupture of the bowel, from a portion of the intestine lying over this hard tumor being injured in her fall, so as to burst and give rise to fatal peritonitis. The tumor was so firmly impacted in the true pelvis, and so nearly filled it, that, after being detached with the knife, it required powerful force to extract it. The wonder was, that the lady did not suffer material inconvenience from the tumor, either in regard to the action of the bowels or the passage of the urine. Mr. Arnott stated, that until a short time before the accident, the patient was accustomed to take exercise on foot and on horseback, and enjoyed excellent health. The tumor had been observed, seemingly of nearly the same size as at her death, for thirty-six years.

In 1808, having been alarmed by an opinion communicated to her that it was cancer, she had the joint advice of Sir Richard Croft and Dr. Denman, who examined it, and merely recommended rest. A section of the tumor exhibits a hard bony structure, with some sub-divisions or lobes, marking, apparently, that it consisted originally of a series of distinct fibrous tubercles, now converted into bone. Professor Daniel has ascertained that there enter into its composition—

Of phosphate of lime	56 parts.
Animal matter	.. 35
Carbonate of lime	5

the remainder being made up with alkaline and earthy salts in minute proportions. Thin slices have been examined microscopically; and the observations have tended to show that it possesses the same structure as bone, osseous corpuscles having been detected in its substance.

Mr. Langstaff concurred with Mr. Arnott in his opinion as to the tumor having been originally of a fibrous structure. He referred to two cases in which death was occasioned by tumors of that nature occupying the true pelvis. In one, the transverse arch of the colon was ruptured from obstruction to the course of the fæces; in the other, rupture at the fundus of the bladder took place, owing to the tumor compressing the neck of the bladder.

Tumor on the exterior of the thorax, communicating with the cavity of the pleura at the interval between the portions of a fractured rib.

Mr. E. Wilson shewed the parts which he had removed in a recent dissection: The subject of the dissection was a child sixteen months old, that had been picked off the streets, and taken to the St. Pancras Infirmary, where she shortly afterwards died. The nurse drew his attention to a swelling situated below the inferior angle of the scapulæ, which he stated had appeared suddenly only two days before the death of the child. Upon pressing this tumor, the contents were easily evacuated, and it disappeared. On proceeding with the dissection, he found a cyst between the ribs and intercostal muscles on the one hand, and the latissimus dorsi and scapula on the other. One of the ribs, on which the cyst was formed, was discovered to have been broken, the edges being ununited and rounded off. Between these portions a small opening, leading into the interior of the thorax, was perceived. When the thorax was next examined, a large accumulation of serum was found occupying the cavity of the pleura, and compressing the lung to a small size.

On the Statistics of Disease and Mortality in the Metropolis. By GEORGE GREGORY, M.D.

THE Act for the Registration of Births, Deaths, and Marriages, passed in 1836, and came into operation on the 1st July, 1837. The earliest fruits of this truly national measure was a valuable document, the first report of the Registrar General, laid before Parliament in 1839. The second result was the publication of the new Tables of Mortality, which commenced on the 5th January, 1840, and are continued weekly. These tables, said the lecturer, constitute a most interesting addition to the stock of our facts on vital statistics. To profit by them, however, some previous information is requisite,

which all may not possess. To supply that preliminary knowledge, to explain the machinery by which the new tables and the modern system of registry are worked out, and to point out the chief results which have been obtained from them, were the objects of the lecture. The limits of the old and present metropolis, its growth from the time of Charles II., the existing population of London, its rapid rate of increase, and the proportion in which the several groups of the population (the young, the adult, and the aged,) co-exist, were the topics first alluded to.

It appears that, in the time of Charles II., the population of London was short of half a million. In the year 1665, the deaths recorded in the bills of mortality were, by plague alone, 68,596; total—97,306, so that more than one-fifth of the population of London died in that year. The Registrar General includes, under the term metropolis, an area of about seventy square miles, extending from Stoke Newington, in the north, to Dulwich, in the south: from Hammersmith in the west, to Woolwich in the east. The extreme distance is nearly ten miles. At the census of 1821, the population of the metropolis, (taken in this extended sense,) was 1,328,671. In 1831 it had advanced to 1,594,890. The rate of increase had varied in the five districts into which the Registrar General divides the town, being in the northern 33 per 1000; in the southern, 21; in the eastern, 20; in the western, 18; and in the central district only 5 per 1000 annually. Calculating a like increase in the years since 1831 (that is 18 per 1000, on an average, of the five districts,) the present population of London is 1,955,000, the increase being such that London annually, besides compensating the deaths, receives and amalgamates into its population 36,000 additional souls, or a town as big as York.

In all parts of the world the births of males exceed the births of females. Mr. Finlaison calculates that for every million of females born there are born a million and fifty thousand males, the proportions being 79 to 83, or very nearly 20 to 21. The disproportion, however, of the sexes rapidly diminishes, so that in all mixed populations the females predominate. In London, in 1831, the proportions were 739,719 males to 855,171 females.

The imperfections in the act, regarding the registry of births, prevent us from knowing exactly how much of the annual increase in the metropolitan population is owing to excess of births above deaths, and how much to influx of *advenæ*. Calculating the births at 30, compared to the deaths as 20, we conclude that there are

70,000 children born annually in London ; and this leads to the deduction that one half of the annual increase is owing to excess of births, and the other half to importation from surrounding rural districts.

The lecturer then proceeded to give a brief sketch of the origin, progress, and decay of the old bills of christenings and burials, prepared by the worshipful Company of Parish Clerks. Due credit was given to them for their efforts, in 1819, to improve the system of metropolitan registration. They spent nearly 1000*l.* in a vain effort to obtain an Act of Parliament for that purpose. The machinery of the recently issued Tables of Mortality (which, it will be remembered, are registers of *births* and *deaths*, not of christenings and burials) was then explained, and the same brought under review, and compared with the results of the old bills, and with the registration of provincial districts. The introduction of the *cause of death* into the schedule prescribed by the Act was a great improvement, for which we stand indebted to the British Association of Science.

The deaths in London in 1838 amounted to 52,698; being at the rate of 1613 per week, 144 per day, six per hour, or one in every ten minutes. This may be considered as a fair average; being at the rate of one death in 36 of the whole population, or 28 per thousand. The deaths since the 5th January, 1840, have fallen short of this average by 100 per week, as was shewn by reference to tables which have already appeared in this journal. The remarkable uniformity in the weekly numbers, as also in the proportion of the sexes carried off, and in the ratio of the young, the adult, and the aged, was next pointed out and illustrated. In all observations on these and other tables of mortality, it must be borne in mind in what ratio these three great groups of the population co exist. The proportion appears to be pretty nearly the same in all countries. On an average of 100 persons, 32 are under fifteen; 62 between fifteen and sixty; and 6 above sixty: that is to say, there are twice as many grown persons as young persons, and six times as many young as aged persons.

The mean duration of human life (technically called the *vie probable et moyenne*) has considerably increased, as is remarkably well shown in the phenomenon so long presented by the bills of mortality, of stationary mortality with increasing population. This improvement in the value of life is perceptible even in the earliest infancy. Between the years 1733 and 1737, the proportion of children in London dying under two years of age was 393 per 1000, while in 1837 the proportion was only 290 per 1000. In London, about half the num-

ber born die before reaching the age of twenty-two. In some rural districts, the half do not die before the age of thirty-six; while, in confined localities and manufacturing populations, the one half of the children born die before attaining the age of eighteen. In Leeds and Manchester, half of the males are dead at the age of eight, and half the females at eighteen. The proportion of deaths in the three groups of the population, specified in the new tables, are,—under fifteen, 40 per 1000; the adult, 16 per 1000; the aged, 97 per 1000. Average, 28. From these data we calculate, that, of the 658 members of which the House of Commons is composed, 13 may be expected to die annually.

The new tables do not afford as yet any materials for determining the relative mortality of the seasons in London. As far as is known we have reason to conclude, that here the healthiest seasons are summer and autumn, the most fatal winter and spring. Under all circumstances, the rate of mortality is influenced by the density of the population; their comparative state of comfort or indigence; and in a considerable degree, also, by the opportunities enjoyed of ventilation and purification. In London, the most unhealthy districts are Whitechapel, Bethnal Green, and St. Giles's; the most healthy are the suburban districts, and the parish of St. George, Hanover Square. Out of 1000 females, living in Whitechapel, there die annually 38; out of 1000, living in St. George's, Hanover Square, there die annually only 17. The proportion of deaths in London, compared to that of rural districts, is as 24 to 18, or 4 to 3.

A considerable portion of the lecture was devoted to an elucidation of the doctrine of Climacterics, or of the disposition in the human body to certain developments at certain fixed periods. The ascending Climacter is 7, 14, and 21, marking the great periods of childhood, puberty, and manhood, were first adverted to and commented on. The descending scale, 49, 63, and 81, were shewn to receive no countenance whatever from statistical investigation. So far from it, these years are peculiarly light in the calendar of mortality. The descending Climacterics are not multiples of 7 and 9, as the Greeks and Romans fancied, but multiples of 10. In London, the most fatal years are 40, 60, 70, 80, 90, and 80. The order varies slightly in other districts, but the disposition to a decennial augmentation of mortality is every where discernible. The correctness of this theory of a decennial Climacter has lately been called into question, but not on sufficient grounds. It was first pointed out by Mr. Rickman in 1831.

The latter part of the lecture was to

have comprised a classification and analysis of the principal forms of disease by which the metropolitan population is carried off, but the lateness of the hour prevented the lecturer from developing fully this branch of his subject. He took occasion briefly to allude to the fluctuations which may be perceived in the prominent disorders which thin the population of London. Hooping-cough, which in the seventeenth century was scarcely mentioned among the fatal diseases of London, destroyed in 1838 more than 2,000 persons. Vaccination, by closing one avenue to death, serves indirectly to open another, as it carries the infantine population forward to that age when it becomes obnoxious to another tribe of diseases. The encephalic diseases of children, and small-pox, which were the great metropolitan scourges in the last century, have now given way to pneumonia, hooping-cough, and scarlatina. The only disease which retains the same place in the catalogue of fatal ailments which it held in 1654, is consumption, which the lecturer seemed disposed to view as the great gulph into which all improvements in medical practice, and all ameliorations in the condition of mankind, tend ultimately to drive the population. If we rightly comprehend the tenor of his concluding sentences, his notion appeared to be, that *natural decay* and *consumption* were the two ultimate modes of death; that the former was every year steadily advancing to assume that place in the list which the philanthropist would desire, but that consumption is still (as it always has been) immeasurably a-head of all other disorders in the tables of mortality, and likely so to continue, in spite of every effort of human skill.

The lecturer divided the complaints which carry off the great mass of the metropolitan population, into four groups. 1. Those which originate in congenital delicacy of frame, or those structural and functional peculiarities impressed on the individual at birth, and transmitted from parent to offspring. To this head belong convulsions, hydrocephalus, infantile pneumonia, croup, and, above all, consumption. 2. Those which result from changes occurring in the body from the mere influence of time, such as apoplexy, palsy, asthma, heart affections, dropsy, mortification, cancer, and natural decay. 3. Those which result from the operation of specific poisons, received into the body from without, and which operate independently both of original constitution and the influence of time; of this kind are typhus, small-pox, measles, scarlet fever, hooping cough, and cholera. 4. Those which originate in accident, or irregularities of diet and

mode of life, or the nature of the occupation or locality. To this class belong childbirth, hydrophobia, gout and rheumatism, erysipelas, ague, violence. Nineteenths of mankind are carried off by the three first classes, and one-tenth by this last section.

ROYAL SOCIETY:

February 13, 1840.

On the Source of Power in the Voltaic Pile.

THE reading of a paper, entitled, "Experimental researches in Electricity, 16th Series." By Michael Faraday, Esq., D.C.L., F.R.S., &c., was resumed and concluded.

The determination of the real source of electrical power in galvanic combinations has become, in the present state of our knowledge of electricity, a question of considerable importance, and one which must have great influence on the future progress of that science. The various opinions which have been entertained by philosophers on the subject may be classed generally under two heads; namely, those which assign as the origin of voltaic power the simple contact of dissimilar substances, and more especially of different metals; and secondly, those which ascribe this force to the exertion of chemical affinities. The first, or the theory of contact, was devised by Volta, the great discoverer of the voltaic pile; and adopted, since it was promulgated by him, by a host of subsequent philosophers, among the most celebrated of whom may be ranked Pfaff, Marianini, Fichner, Zamboni, Matteucci, Karsten, Bruchardat, and also Davy; all of them bright stars in the exalted galaxy of science. The theory of chemical action was first advanced by Fabroni, Wollaston, and Parret; and has been since farther developed by Oersted, Becquerel, De la Rive, Ritchie, Pouillet, Schonbein, and others. The author of the present paper, having examined this question by the evidence afforded by the results of definite electro-chemical action, soon acquired the conviction of the truth of the latter of these theories, and has expressed this opinion in his paper published in the *Philosophical Transactions* for 1834.

The author, after stating the fundamental doctrine laid down by Volta, proceeds to give an account of various modifications in the theory introduced by subsequent philosopher, and of different variations in the views of these who, in the main, have adopted the chemical theory. Being desirous of collecting further

and more decisive evidences on this important subject, he engaged in the series of experimental researches which are detailed in the present memoir.

It is assumed, he observes, by the advocates of the contact theory, that although the metals exert powerful electromotive forces at the points of mutual contact, yet in every complete metallic circuit, whatever be the order or arrangement of the metals which compose it, these forces are so exactly balanced as to prevent the existence of any current; but that, on the other hand, fluid conductors, or electrolytes, either exert no electromotive force at their place of contact with the metals, or, if they do exert such a power, the forces called into play in the complete circuit are not subject to the same law of compensation as obtains with the circuits wholly composed of metallic bodies. The author successfully combats this doctrine, by bringing forward a great number of instances, where certain fluids, which have no chemical action on the metals, with which they were associated in the circuit, are in themselves such good conductors of electricity, as to render evident the current which could have arisen from any contact of the metals, either with each other or with the fluid; the evidence of their possessing this conducting power being their capability of transmitting a feeble thermo-electric current from a pair of plates of antimony and bismuth. The following he found to be fluids possessing this property in a high degree; namely, a solution of sulphuret of potassium, yellow anhydrous nitrous acid mixed with nearly an equal volume of water, very strong red nitric acid, and a mixture of one volume of strong acid with two volumes of water. By employing the solution of sulphuret of potassium as an electrolyte of good conducting power, but chemically inactive with reference to either iron or potassium, and associating it with these metals in a circuit, formed by two test-glasses containing the solution, into one of which was immersed a plate of platina and a plate of iron, and in the other two plates of platina; and the circuit being completed by wires of the same metals respectively, joining the iron-plate in the first glass with one of the platina-plates in the second, while the other two platina plates were united by platina wires, interrupted at one part by a short iron wire which joined their ends;—it was found by the test of an interposed galvanometer, that, as no chemical action took place, so no electric current was produced; yet the apparatus thus arranged could transmit a very feeble thermo-electric current, excited by slightly raising the temperature of the wires at

either of their points of contact. Hence, the inference may be drawn, that the contact of iron and platinum is of itself productive of no electromotive force. On the other hand, the author shows, that the interposition in the circuit of the smallest quantity of an electrolyte, which acts chemically on either of the metals, the arrangement remaining in all other respects the same, is immediately attended with the circulation of an electrical current far more powerful than the thermo-electric current above mentioned. A great number of combinations of other metals were successively tried in various ways, and they uniformly gave the same results as that of iron and platina. Similar experiments were then made with various metallic compounds, and also with other chemical agents; and in all cases the same general fact was observed; namely, that when no chemical action took place, no electrical current was excited; thus furnishing, in the opinion of the author, unanswerable arguments against the truth of the theory of contact. The only way in which it is possible to explain these phenomena on that theory, would be by assuming that the same law of compensation as to electro-motive power is observed by the sulphuret of potassium, and the other fluids of corresponding properties, as obtains in the case of the metals, although that law does not apply to the generality of chemical agents; and in like manner, different assumptions must be made in order to suit the result in each particular combination, and this without any definite relation to the chemical character of the substances themselves; assumptions, which no ingenuity could ever render consistent with one another. At the conclusion of the paper, the author describes some remarkable alternations in the phenomena which occur when pieces of copper and silver, or two pieces of copper, or two of silver, form a circle with the yellow sulphuretted solution; and which lead to the same conclusion as the former experiments. If the metals be copper and silver, the copper is at first positive, and the silver remains untarnished; in a short time the action ceases, and the silver becomes positive, at the same time combining with sulphur, and becoming coated with sulphuret of silver; in the course of a few minutes, the copper again becomes positive; and thus the action changes from one side to the other in succession, and is accompanied by a corresponding alternation of the electric current.

VACCINATION EXTENSION BILL.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward to you, for insertion in the MEDICAL GAZETTE, the following copy of resolutions agreed to at the last meeting of the Medical Institution of Liverpool, on the subject of the Vaccination Extension Bill at present before parliament.—I am, sir,

Your obedient servant,

JOHN SUTHERLAND, M.D.
Secretary.

Liverpool, 4th April, 1840.

At a meeting of the members of the Medical Institution of Liverpool, held on Thursday, 26th March, 1840, James Dawson, Esq. President, in the Chair, it was resolved—

1st. That the practice of vaccination offers a very sure means of preventing small-pox, and is not attended with any serious risk, whilst inoculation is not more sure as a means of prevention, and is attended with great danger: it is, therefore, the opinion of the Medical Institution of Liverpool, that the practice of inoculation by all parties, medical men as well as others, should be discouraged by penal liabilities, in the bill now before parliament, entitled, "An Act to extend the practice of Vaccination."

2d. That as the efficacy of vaccination depends very much on the efficient performance of the operation, the Medical Institution of Liverpool is of opinion that it is of great importance that such measures should be adopted as will prevent or discourage ignorant or unqualified persons from taking upon themselves the performance of an operation which, if unsuccessful in its results, is worse than useless; inasmuch as it gives the semblance of security where there is no security whatever.

out their co-operation, but little could be effected in the way of improvement. Let the public bear in mind the extent to which they are dependent on the medical profession for health and life, the greatest of worldly blessings. Let them recollect how readily medical opportunities are abused, and the temptations to their abuse; the mysteries of the sick-chamber*, the nursery, and the lunatic asylum; all affording fearful opportunities to the unprincipled practitioner, to betray his trust for the sake of lucre—not to speak of the minor instances in which fraud and imposture can be resorted to. They should also remember that they are dependent, not only on the conscientiousness of their medical attendant, but also on the honesty of the apothecary or chemist. Without chance of detection, it is in his power to substitute for the ingredients prescribed, others of inferior cost and efficacy; for, in a compound medicine, not even a member of the trade could perceive the change. Yet life itself may hinge on the difference.

It is not by persons of a respectable rank of life (habituated to expensive luxuries) seeking the cheapest way of accomplishing their object, where the most important of all its necessities are concerned, and cutting down the medical attendant to half-a-crown per visit, or bargaining with the apothecary as with a fish-woman, that educated and skilful practitioners are to be obtained for their service: there will, no doubt, be always plenty of physicians, surgeons, apothecaries, and druggists†; but the public will have occasion to rue the day that, by depreciating medical practice, they cause its trusts to pass into the hands of the ignorant and unprincipled. To be brief, in a country like Britain, where money is almost the test of respectability, the medical profession must be properly remunerated, if that profession is to be an occupation for the better ranks, and not for the dregs of the community. As in America, the recovery of his fee ought to be as far facilitated, and the scale of remuneration at least as large, in the case of the physician‡ or surgeon,

OBSERVATIONS ON MEDICAL REFORM.

BY A PROFESSOR IN THE SCHOOL OF PHYSIC IN IRELAND.

THE observations on this subject, in a preceding number of the LONDON MEDICAL GAZETTE, had reference to the share that the legislature ought to take in the matter. That which appertains to the parties, the profession and the public, is of still greater importance, since, with-

* Solicitations to midwifery practitioners to procure abortion, for a high fee, are not obsolete. It is still easier to accomplish infanticide by connivance of the accoucheur.

† An English lady, attended for the first time by a Dublin accoucheur, could scarcely be persuaded that she could have the milk in her breasts for suckling her infant, without swallowing a number of white mixtures termed "milk-draughts;" which had been declared, in England, to be indispensable for the purpose.

‡ Law and usage are at variance as to the legal rights of physician and surgeon to recover their fees. Usage makes a distinction, in this respect, between the departments; but law includes surgery in physic—"forasmuch as the

as in that of the attorney; and, unlike what it is in Britain at present, juries ought to lean to the just claims of medical men, and to the support of their interests, as much as they now incline the opposite way. With respect to public institutions, it ought to be recollected that the medical man is a grade above the providore, or housekeeper, in rank; and this should be considered in settling his salary. Woe to the public in the end, if the present system of cheapening, in all medical matters, shall continue.

Apothecaries' prices ought to be arranged by a medical board, on the estimate that the medicines are procured of the best quality, and the compounds of a known* strength. In arranging the schedule of prices, full allowance should be made for cost of education, the occupation of time, expense of establishment, &c., which the public leave out of account altogether, and expect to have an assortment of medicines kept ready for their use, with attendants and messengers, at the cost of merely a discount on the price of the portion of raw article sold. For instance, they think that the apothecary ought to sell an anodyne draught for, at the utmost, not more than double the price of the cinnamon water and laudanum it contains, never considering that the cost of the ingredients is to the apothecary of as little relative importance as that of the ink and paper to a scrivener. In order to meet the imposition, as they term it; they occupy ten-fold the time, and take ten-fold the trouble the price is worth, in order to get the ingredients at a druggist's and make them up at home, at the risk of total failure in the remedy, or of being, perhaps, poisoned.

There ought to be, as health or life is valued, a steady co-operation between physicians and the public to support those pharmaceutical establishments exclusively, where the measures requisite for the public weal shall be pursued, and the proprietors of which have subscribed and adhered to the regulations. Any attempt at underselling ought to be met as a dishonest proceeding, equivalent to that of deterioration or adulteration, and by a protest, on the part of the medical attendant, against the establishment. If the public are afraid that high prices might raise the apothecaries too nearly to a level with the huxter's bill, let them recollect that "a little and good" is a saying more true, with

respect to medicine, than any thing else, and that if they consented to use a quarter of the quantity of drugs, (consumed at home or in charitable institutions,) and at four-fold the price, the trade would be as well, and themselves incomparably better, off.

Many persons are apprehensive that ere long all medical business will pass into the hands of the general practitioner, and that the apothecary will supersede the physician and surgeon; an opinion as strongly entertained, and the evils of general practice as loudly deprecated, a century and a half ago* as now, and still the crisis has not arrived yet. Those who look to the signs of the times must, indeed, see that there is no department of the profession less likely to be in vogue after a few years than that of the extemporaneous compounder. There are daily accumulating such numbers of palatable, and, indeed, excellent, ready-made compounds, at the establishments of respectable chemists, that it is more likely that the physician or surgeon will draw on these resources instead of the apothecary's dispensary, or manage the disease on, what are termed, homœopathic principles, than that he will be superseded by a less skilful practitioner, merely because the latter is licensed to combine medicines *pro re natâ*. The public are learning that there is no charm in medicine, and that drugs are to the physician what his instruments are to the surgeon—indispensable tools, and nothing but tools—more likely to do mischief than good if not properly handled. It is not the precise form of the mixture or the pill, but the "where" and the "when," that its active principles (almost)—no matter how compounded, are to be brought into operation, that form the nicety of treatment. The public once thought the physician "cured" a fever, the surgeon "set" a broken leg, and that the accoucheur "delivered" in his vocation. That day is gone by; all are known now to be but sentinels on the efforts of nature, and, in the great majority of cases, to accomplish their objects by passive or negative treatment, medicines are necessary—a few, and the best of their kind.

EXTRA-UTERINE FŒTATION.

A REMARKABLE example of this is recorded by Dr. Spaeth, in the *Medicinisches Correspondenz-Blatt*, in which portions of the fœtus were discharged per anum for twenty years afterwards.—*American Journal*.

science of physic doth comprehend and contain the knowledge of surgery, as a special part and member of the same."—Stat. 32 Hen. 8, cap. 40.

* According to Mr. Guley (Magendie, p. 85.) different specimens of "prussic acid," sold for medical use, varied as 4 to 1 in strength.

* See the essay of Jonathan Goddard, M.D., Fellow of the College of Physicians, in the reign of James II., as published in the Harleian Miscellany.

TESTIMONIAL TO SIR BENJAMIN BRODIE.

A MEETING was held at St. George's Hospital on the 2d inst., for the purpose of considering what testimony of respect it would be proper to pay to Sir Benjamin Brodie on his retirement. Mr. Fuller took the chair, and the meeting was numerously attended. Dr. Chambers, Sir Charles Clark, and many other distinguished members of the profession, were present. We have not heard the nature of the testimonial which it is proposed to offer on this occasion.

CUBA HONEY AND WAX.

AMONG the insect tribe, the bee furnishes two important articles of export, in its wax and its honey. In the higher grounds, and the cultivated regions of the island, the honey is of a delicious quality; but in many of the lower districts, especially near the coast, where there are shrubs and plants of a poisonous nature, the honey becomes also pernicious from the bees having fed on their flowers. The inhabitants, nevertheless, persist in making use of it for sweetening their coffee, at the expense of nausea and headache to those who have not been accustomed to its use. The negroes eat it in abundance; and, in some places, the dogs are said to feed on it exclusively. There is another sort, supposed to be indigenous, called the *abeja criolla*, much lighter in the colour, and with a sting so short, that it scarcely makes itself felt. It builds its hive in hollow trees in the interior of forests or in clefts of the rock. Its wax is of a dark colour, but of balsamic quality, and considered useful in healing wounds and reducing tumors, particularly such as have become callous; that which is obtained from the interior part of the hive being preferred, from its being of a more powerful aroma. The honey is also darker in quality than that produced by the common bee; but its flavour, though strong, is agreeable. It often requires great courage to climb to the places in the rocks where their hives are formed; but the natives of the country are accustomed to it, and pursue it with all the ardour of a field sport. In those districts where this dark-coloured wax is produced, it is made into candles for the use of the neighbourhood, without being bleached.—*Cuba: with notices of Porto Rico, and the Slave Trade. By David Turnbull, Esq.*

YELLOW LIQUOR AMNII.

DR. PURDON, in a paper read before the Dublin Obstetrical Society, mentioned a case, in which, on rupture of the membranes in a woman affected with jaundice, the liquor amnii exhibited a deep yellow colour.—*Dublin Journal.*

PORTRAIT OF DR. CHAMBERS.

ON the retirement of Dr. Chambers from St. George's Hospital, a committee was formed by his pupils for the purpose of offering him some tribute of respect. It was decided to have a portrait, by Phillips, (three-fourths length), to correspond to that of Mr. Hunter, and to be placed in the Board-room of the Hospital.

LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.
Surgeon to the St. Marylebone Infirmary.

DISEASES OF ARTERIES.

ANEURISM—*continued.*—*Prognosis*—*Treatment by Valsalva's Method*—*by Cold*—*by Compression*—*by Ligature at the Sac*—*above the Sac.* *Consequences of the Ligature*—*Hæmorrhage*—*Enlargement of Tumor, Gangrene*—*Torsion, Mucure, &c.*—*Ligature beyond the Sac*—*Agents acting upon the Sac*—*Results of different Methods.*—**TRAUMATIC ANEURISM**—*Symptoms, Prognosis, Treatment.*—**VARICOSE ANEURISM**—*Symptoms, Treatment.*

Prognosis.—The prognosis in aneurism is influenced by many circumstances; generally it is a very serious disease; abandoned to itself, the sac may rupture, and death may follow; still, spontaneous cures do occasionally happen, but it is an event which cannot be calculated upon in a particular case. The tumor may inflame, ulcerate, and, instead of yielding blood, may give out pus, and a radical cure may follow. It may mortify, the mortification extending to the whole sac, and thus be cured. Again, tumors presenting all the characters of aneurism may disappear under compression. Generally speaking, every aneurism seated so near the trunk as to prevent the application of the ligature, or compression above it, is absolutely incurable. Still, every aneurism situated thus near to the trunk is not absolutely fatal; the injured point of the artery usually corresponds more or less exactly to the centre of the tumor; therefore, in certain cases, where the ordinary operation is

impracticable for want of space, it is possible to cut down upon that point, and apply ligatures. We must not, however, be understood to say that aneurisms are as much less serious as they are removed from the trunk; the situation of the anastomosing branches has much influence on the result. The cure of an aneurism, as a general rule, requires that the arterial trunk should be exposed; the deeper the trunk, and the more difficult to get at, the more is the danger. The cure of aneurism requiring the obliteration of the arterial trunk upon which it is seated, the circulation must be carried on through collateral channels; now, an aneurism, especially when the tumor is large, embarrasses the circulation through that artery, and the collateral channels are dilated; therefore it is that the chances of success from operation are greater when an aneurism has existed long enough, and has been large enough to prepare these vessels. Still, recent aneurism has its favourable circumstances; in such a case compression may be tried; in a large tumor it should not.

In fact, the prognosis of aneurism is more or less favourable, *cæteris paribus*, according to the age, the temperament, and the present bodily health of the patient; these circumstances must never be lost sight of, because they may have great influence upon the result of the operation necessary for the cure of the disease.

Treatment.—That aneurism spontaneously produced, may be spontaneously cured, has been abundantly shewn. For many years it was believed that it might happen without obliteration of the artery, but subsequent experience has shewn, that whether artificially or naturally cured, the cases are rare in which the permeability of the artery remains. This belief no doubt arose out of a conviction which long existed, that the obliteration of a principal artery caused gangrene of the limb, and the non-occurrence of this accident in many cases where aneurism had been cured,

could only be explained by assuming that though the aneurism was cured, the obliteration of the artery was a consequence. At present we know that to cure an aneurism we must obliterate the artery, and, therefore, our means must be directed to accomplish this object.

Valsalva's name is associated with a mode of treatment long and extensively employed; it comprised those means best calculated to lessen the energy of the heart's action, to diminish the quantity of blood circulating, and to favour coagulation in the sac. For this, very rigid diet, a very small quantity of fluids, absolute rest, were essential; with these were associated laxatives, digitalis, and frequent small bleedings. Many cases are recorded, in which the further progress of internal aneurism has been arrested under this treatment; but in how many has it utterly failed! It may be carried so far indeed as to lessen the chances of cure, by lessening the plasticity of the blood, and increasing the general irritability; but in internal aneurism we have no mode of treatment which promises better. Lately, another means has been associated with these, the exhibition of the acetate of lead, which, it is said, increases the tendency of the blood to coagulate, and cases of cure are mentioned, but I have never used it myself, or seen it used by others; and, therefore, I can only say, that its power of restraining hemorrhage appears to depend upon some such power, and that it is worth a trial in cases internal aneurism.

Bartholin strongly advised the use of cold (whether in the form of ice, iced water, refrigerants, or other mode), applied directly to the tumor, but it was, and is, still used principally as an auxiliary to the preceding method. Cases are recorded in which it has been successfully employed, but again I say, where the ligature can be properly applied, we ought not to rely upon cold; it has produced gangrene, and other serious inconveniences.

In the present day, we do not follow the plan of Severinus in applying the actual cautery to the tumor.

Guattani extensively employed compression upon the tumor, and along the course of the artery above the aneurism; it has been also circularly applied. Guattani's method has all the advantages which can be derived from compression. Compresses are applied to the tumor and along the artery, and a bandage is firmly and equably applied to the whole limb; cold lotions are applied upon the apparatus, and other means, as in the Valsalva treatment, are associated with it. That this means of treatment has been often successful is perfectly true; but many patients cannot support it. The numbing sensation which it sometimes occasions is

very distressing to some persons. In the compression, as exercised by Guattani, there is another serious inconvenience; it diminishes the energy of the collateral circulation, or even prevents its development, and so prejudices the success of any operation. Although Guattani may have cured four out of twenty cases, its efficacy seems to me very doubtful. The bandage is apt to loosen, and its success is thus defeated. Methodically applied, it will fail in bad cases, and the ligature must be employed; for these reasons at present it is rarely used.

Vernet fancied that compression below the tumor would cause, as in the operation of Brasdor, a coagulation of blood in its sac. In this he was deceived, and the operation was soon abandoned.

The *ligature* has been employed in different ways in the treatment of aneurism: the aneurismal sac has been opened, and the open mouths of the artery have been tied; the ligature has been applied at a distance, between the tumor and the heart, without meddling with the tumor at all; it has been applied between the sac and the capillaries. The first plan of applying the ligature is almost completely abandoned in the present day: when used, the method of Gauntani has been followed. A tourniquet has been applied, or the operator has been satisfied to trust to the thumb of an assistant. The operator, satisfied that all pulsation in the tumor has ceased, incises the integument in the course of the artery; the incision extends a little beyond the limits of the tumor; he carefully dissects down upon the sac, and opens it in all its length; the coagula are then removed, and the arterial openings are sought for; a sound or probe may be passed into them, the artery raised, and a needle, carrying a thread, passed under it: it should not be placed too near the sac, for fear of including a diseased part; another ligature is placed below the sac, the wound is then sponged out, the ligatures brought to the angles, and the whole healed, if possible, by first intention. With respect to this operation, it is necessary to make a few remarks: if the artery above the tumor appear much diseased, a flat ligature should be used. Hæmorrhage is frequent, sometimes because the coats quickly give way under the ligature. Violent inflammation of the part often occurs. Indeed, if we refer to the cases on record, it will be seen that the operation is often difficult and painful, that bad consequences frequently follow it, and that these disadvantages are not compensated for by any advantage; and it is abundantly proved that the ligature above the tumor is a much more successful mode of treating aneurism than by opening the sac.

The operation of *tying the artery above the sac*, when practicable, is the treatment almost always employed in the present day for the cure of aneurism, the sac being left entire. Guillemeau, it is believed by some persons, operated in this way; but this is an incorrect opinion: he followed the method of *Ætius* and *Philagrius*. The course of the artery was marked out; it was cut down upon, tied with two ligatures, and the artery divided between them. All fear of hæmorrhage being thus removed, the sac was opened, and, its contents being turned out, two ligatures were placed upon the openings into the sac (Guillemeau, *Œuvres de Chir.* chap. 6, p. 698). The principle of the present operation was unquestionably acted upon by *Anel* in a case of aneurism at the bend of the arm, (*Suite de la Nouvelle Méthode de Guérir la Fist. Lac.* Turin 1714, 8vo. p. 255.) We cannot say that he was aware of the many advantages of this method. He tied the artery, it is true, near the aneurism; and he left no precept on the subject: however, as in that case, it was not necessary to tie the artery at a greater distance from the tumor, we cannot say that in a different case, a popliteal aneurism for instance, he would not have proceeded to the middle of the thigh. The glory of applying this principle, and demonstrating its excellence, certainly rests with *John Hunter*. *Desault*, in the month of June, 1785, tied the popliteal artery *immediately above the tumor* for aneurism *in the ham, without opening the sac*: the nineteenth day a great quantity of sanious and grumous matter escaped from the wound. In December, of the same year, *Hunter* performed his operation, placing the ligature far away from the sac before the artery passed into the adductor canal; and unquestionably this is the great—the important, principle of success in the treatment by ligature. *Desault's* object in placing the ligature so near the tumor was, no doubt, to preserve as many collateral vessels as was practicable; but, then, at what a cost was this problematical advantage gained! The operation was difficult, from the depth of the artery and the contiguity of the sac; the ligature was likely to be, and really was, placed upon a diseased point of the artery; the tumor was near enough to become inflamed under the irritation, and this actually happened. *Hunter* passed under the artery four ligatures, a little removed from each other, and tied them at different degrees of tightness, so that the ligature nearest the tumor was the only one which totally intercepted the passage of the blood, the others merely moderating the current; the three extra ligatures he afterwards abandoned as useless, if not injurious.

Though French surgeons seek to detract from *Hunter*, by assuming that *MM. Anel*

and *Desault*, *Leberus* and *Van Hespel*, had already employed this method, no reasonable person will refuse to admit, that to *Hunter* alone must be accorded the merit of having established, upon sound principles, the success of the operation. With him success was no matter of doubt. He knew how serious, how doubtful, was the operation of opening the sac; he knew how great was the risk of finding a diseased artery near the tumor, whilst it might be comparatively healthy at a distance; he knew the power of the absorbents to remove the contents of the sac. The operation of *Anel* had not been followed; it had been condemned by *Molinelli*, *Verbrugge*, and others. Had not *Hunter* directed his mind to the subject, it is extremely probable that a similar fate would have attended that of *Desault*. To *Hunter*, therefore, must in fairness be conceded all the honour of the operation of tying the artery above the sac.

In performing this operation certain rules must be attended to. You cannot always place the ligature at the same distance from the sac; but it is wise to be as far removed from it as is practicable, that there may be more chance of finding it healthy: and it is also desirable to expose the artery where it is superficial, as the operation is thereby facilitated. We must also be guided to some extent by the going off of collateral branches, as the maintenance of the circulation in the lower part of the limb will, to a certain extent, depend on this.

The following are the results of the ligature placed above the sac:—Usually pulsation ceases as soon as the ligature is tightened; sometimes it continues, but is more feeble; in other cases it is renewed after a few days, lasts for a few days more, and then ceases. When the pulsation continues, it is evidence that the collateral channels bring the blood into the artery before it reaches the sac, or very soon afterwards, as in fig. 1, which was a popliteal aneurism; sometimes, even when the pulsations continue, if feeble, the case does well.

When the case does well the tumor diminishes in bulk, and becomes harder; if pain existed, it gradually disappears, and a hard nucleus is all that remains. Immediately after the ligature is tied the temperature of the limb begins to decline; but, in other cases, some time afterwards the temperature is raised, and this is always a good sign; it shows that the capillary circulation is active. As the arteries dilate this symptom is gradually dissipated. In some cases the diminished temperature continues for many days, the limb remaining numb, almost insensible, and decoloured; then we have fear that the circulation will not be re-established, and that mortification will set in. The general symptoms

FIG. 1.

which follow the operation upon a large artery near the trunk are very variable; sometimes seeming to depend upon the sudden change brought about in the circulation, sometimes produced by spasm. The hardness and frequency of the pulse, heat of skin, suffused countenance, headache, vertigo and oppression, agitation and delirium, belong to the first cause; paleness, trembling, small pulse, rigors, hiccup, nausea, subsultus, and syncope, to the second.

The accidents which may follow the operation are, *secondary hæmorrhage, increase of size of the tumor, and rupture, gangrene of the tumor, and gangrene of the limb.*

After this operation the dressing should be simple. The limb should be so placed as to relax slightly the artery; it should be surrounded with flannel bags, containing warm salt, but they should not be too heavy, and the limb should be placed so that the heel shall be the highest point; this will facilitate the return of blood. It may be still further assisted by gently passing the hand equably up the limb, so as to give the subcutaneous veins mechanical assistance to expel their contents.

Consequences.—For some time the patient should not make much use of the affected limb, for hæmorrhage has in more than one case been the consequence of this indiscretion.

Hæmorrhage.—Taking 201 cases, in which the artery was tied above the tumor, I find hæmorrhage to have occurred in 34, or 1 in 6—happening, usually, from the sixth to the twenty-fourth day: at the earliest, it has happened on the first day; at latest, on the sixtieth: the total loss amounted to 46, or 1 in 4. If the hæmorrhage occur from that portion of the artery which is continuous with the sac, strong pulsation in the artery or the tumor often precedes it. It may be suspended by making pressure between the wound and the tumor, and there may not be room for the application of a ligature at the point; plugging

is then the only resource. The difficulty might arise in inguinal aneurism.

Increase of tumor.—In a small number of cases, spite of the ligature, the tumor will continue to enlarge. It may happen from the ligature being insufficiently tightened; from removing it too soon; from including some of the adjoining soft parts in the ligature; but generally from a collateral vessel communicating in the immediate vicinity of the sac, as in the figure given above. In a given case it may be difficult to discover the cause. If we believe the ligature to be slack, it should be tied a little higher. If, says Hodgson, in a case of secondary aneurism, we can get rid of the pulsation by making pressure just above the tumor, the artery should be tied there. If we are unable to discover the cause, and if, in defiance of bleeding, cold, and compression, the tumor continues to enlarge, the sac should be opened as already described.

Gangrene.—Gangrene may seize the sac when a tumor is very large, or it may suppurate. These accidents may happen before the ligature comes away, or after. When the mortified sac is ruptured, and hæmorrhage comes on, recourse must at once be had to amputation, if the patient has strength to bear it. If there be no hæmorrhage, but, instead of it, a serous, putrid, or sloughing discharge, we must use proper means of treating this condition, which is usually followed by profuse suppuration, to sustain which the patient's strength must be kept up. When gangrene affects any portion of the limb beyond the tumor, amputation is our only resource, and we cannot always wait for a line of demarcation to impose a limitation to the extension of mortification.

Torsion, machure, &c.—Other means have been used for the purpose of obliterating the artery above the sac. The vessel has been exposed; a tenaculum or needle is passed under it; the needle is then twisted

as a rope is twisted with a stick, to tighten it, around a bale of goods—the number of revolutions to depend upon the size of the artery; the wound is then healed by first intention, no foreign body being left between its lips; and “the vessel as surely obliterated as if surrounded by a ligature,” and there is no fear of hæmorrhage. Thierry and Lieber propose this operation, which, curious enough, is in principle one of the earliest methods of treatment known, and we owe it to Rufus. It has been transmitted to us by Ætius in the following lines:—“*Si vas unde emanat sanguis profundum fuerit, ubi situm ejus et magnitudinem diligenter perspexeris, noverisque numquid vena sit an arteria, vas immissa volsella extendemus et moderate circumflectemus,*” &c. This text is copied by Galen, in speaking of torsion as a substitute for the ligature in the treatment of aneurism. All that need be said is, that if the vessel be healthy there is no fear from the ligature; if it be diseased, there is much danger of its fairly giving way under the twisting process. The artery is much exposed, separated from its connection, and in many situations the operation is impracticable.

Again, Mannoir and others have employed the “machure,” or cutting with a forceps, at several points, the internal and middle coats of an artery. The result of experiment shows, that this process will commonly obliterate arteries of middle size, but will often fail in large ones; and it appears to me to be open to the same objection as the last operation.

Pins and needles have been used for the same purpose, but the objections made to them, when speaking of hæmorrhage, apply with full force here. I make the same objection to the seton and galvanism, as applied to the canal of an artery; if you expose the artery and act upon it, you may obliterate it by either agent, but with less certainty than the ligature; if you do not expose it, there is no security that the agents are applied to it.

Ligature beyond the Sac.—When Vernet proposed the employment of compression beyond the sac, for the cure of aneurism, he clearly paved the way for the proposition of Brasdor, to place a ligature in the same situation, for the same purpose; but it does not appear that he did more than suggest its adoption. The failures in the cases of Deschamps and Sir Astley Cooper were not calculated to bring it into favour; so thought Allan Burns, who says, “that the operation is absurd in theory, and that the result has shewn it to be fatal in practice.” This conclusion was come to upon very insufficient data, and we are now, when there are on record fifteen cases in which the operation has been performed, in a much better condition to estimate its value.

The objections which have been made to it are, that there is danger of the tumor increasing rapidly after the operation: to this objection it may be answered that, on the contrary, the tumor has been diminished and shrivelled; that aneurismal arteries have been obliterated below the sac, while the tumor still continues to enlarge: this has not been found to occur unless a large collateral branch be given off immediately below the tumor, and thus maintained the circulation in it. Mr. Guthrie, with reference to this subject, mentions a case in which Warner amputated a limb; the principal artery, though terminating in a cul de sac, became aneurismatic, and was cured by ligature above; a second aneurism appeared above the ligature, again tied, again cured; a third tumor formed; a third time the artery was tied, and the aneurism cured. But this is a very exceptional case, and cannot serve for comparison. Again, it has been urged, that though it cannot be denied that the operation has in some cases succeeded, the result cannot be attributed to coagulation of the blood in the sac, or to its subsequent removal by absorption, but to inflammation and suppuration excited in the sac by the ligature. Now, even if the cure were procured in this way, it would not be a reason for the proscription of the operation; I can only look upon this operation as an exceptional one, to be performed only when it is impossible to apply a ligature between the tumor and the heart. In fact, besides the common carotid, and the external iliac, above the epigastric, where can it be applied with a chance of success? The operation has been performed with success in aneurism of the carotid, by Wardrop; with temporary success by Lambert; with complete success by Professor Bush; without success in another case by Wardrop; with partial success by Montgomery. In those cases no branches were given off between the tumor and the ligature; Dupuytren believed that it was desirable that a small branch should be given off to prevent the chance of the tumor bursting. Wardrop, though he believed that the most favourable condition was that in which no branch was given off between the tumor and the ligature, persuaded himself that the existence of even more than one did not necessarily prevent the success of the operation; he adopted the opinion of Home, and believed that to obtain the cure in aneurism it was sufficient to diminish the impulse of blood. In a case of aneurism of the femoral, just below Poupert's ligament, Deschamps tied the artery below the tumor: the tumor continued to enlarge, a new operation was required, the patient died. Sir A. Cooper, in a case of aneurism extending to the commencement of the common iliac,

tied the external iliac; the tumor burst into the peritoneal cavity. Mr. White tied the femoral below the tumor, in a case where there was a very large aneurism of its upper part; there was no change in the tumor, but the patient died of erysipelas. In the case of Mr. James, in which he tied the aorta, the ligature was first placed on the internal iliaes, below the point where the epigastric and circumflexa ilii were given off: these results are certainly not encouraging. The operation has been performed for the cure of aneurism of the innominate: the carotid was tied by Mott; at the end of a month the tumor had disappeared; the patient died of suffocation eight months after: the sac within the chest was still large, the subclavian was permeable. Mr. Key, under similar circumstances, tied the carotid: the patient died a few hours after. Mr. Evans tied the carotid, and after much peril for a year, during which abscesses formed, the patient recovered; but the evidence is yet wanting to prove that it was aneurism of the innominate. Mr. Wardrop, in a case in which he conceived the right carotid was obliterated, tied the subclavian beyond the scaleni muscles: at the end of thirteen months there was apparent cure; yet a new bilobed tumor was manifest at the base of the neck: the patient died two years after: the innominate sac was lessened in one direction, increased in another, and the carotid was permeable. A man had a tumor, apparently proceeding from the right subclavian: Dupuytren tied the axillary immediately below the clavicle: for some days the tumour diminished; on the eighth there was hæmorrhage from a small ulceration in the tied vessel, which caused death. Mr. Fearn had better success.

Although I am disposed to regard this as an exceptional operation, to be resorted to only when the artery cannot be tied between the tumor and the heart, yet I freely admit that there are situations where it should hold more prominent place; as an inguinal aneurism extending in the iliac fossa. We must choose between ligature above the tumor, with all its difficulty, and this operation: a similar question may arise where the subclavian is affected in its middle third.

Agents acting upon the Sac.—We have now to consider certain means, which I have recommended, for acting directly upon the aneurismal sac, without injuring to any extent the cutaneous integument. I found that objections, such as I have already stated, attached to the employment of needles, seton, or galvanism, in the course of an artery—the uncertainty of implicating the artery itself. I then employed these agents upon the sac itself, and satisfied myself that either of them, but particularly

the two last, were capable of causing inflammation of the sac, and coagulation of its contents, provided the sac were not too large and too near the heart. A case was described, a few months since, in the Philadelphia Journal, in which a sac was obliterated by the insertion of a single needle. A case occurred in the practice of Mr. Keate, in which galvanism was passed into the tumor from a dozen pair of plates, the current being directed along two needles (inserted into the sac) by Mr. Faraday. The case was one of enormous carotid aneurism: at the first application, the contents were fluid, but soon after a portion of the tumor became firm. A second time the galvanism was applied; the firmness increased, and the progress was satisfactory—the patient died suddenly from the bursting of an aortic tumor: but the examination satisfied Mr. Keate that the carotid tumor would in all probability have done well. This plan has a material advantage—it is attended with no risk, and if it fail any other agent may be used without prejudice.

Result of different methods.—Taking a very large number of cases collected from periodicals and from classical works on the subject, I find that the method of Valsalva was tried five times, of which four cases were successful, but the time occupied was very long; that the *refrigerant and styptic* plan was tried thirteen times; that it succeeded in seven, and that recourse was had to the ligature in four cases; that *compression* between the tumor and the heart was employed in thirteen cases; that in seven of them recourse was afterwards had to the ligature, that in five it succeeded; that in five cases *compression* was applied to the tumor, that it succeeded once, and failed four times; that *compression* upon the whole limb was applied in five cases, of which three followed bleeding; that in three cases it succeeded, that recourse was had to the ligature in the fourth, and that the fifth died; that the mode of compression is not indicated in eighteen cases, of which eight succeeded, and in the other ten recourse was had to the ligature; that in five cases *compression* was associated with refrigerants; in two it succeeded, in three the ligature was resorted to; that in 31 cases, the old operation of cutting down upon the sac and applying ligatures there, was employed, that it succeeded in 23 cases, and failed in 8; that the Hunterian operation was performed in 171 cases, that in 126 it succeeded, and failed in 45; that the operation of Brador has been performed fifteen times, and has succeeded in four. What has been the comparative success of torsion, refoulement, &c., I am at this moment unable to state.

Of these three great methods for ob-

taining the obliteration of an aneurismal artery, that which is *directed to the tumor alone* has, up to the present moment, been the least efficacious; that which is employed *above the tumor* is the most sure; some of the means included in that method have been employed only on brute animals, and are too inconvenient to be adopted in practice; such are the seton, acupuncture, refoulement, and internal plugs without ligature, and to these may be added machure, and in many cases torsion: that which is employed beyond the tumor, *the method of Brasdor*, is a resource to which we must not recur, unless the obliteration of the artery between the aneurism and the heart be impossible, and cold and compression have failed.

As to particular methods, there can be no doubt, that, in general, for the obliteration of the artery, compression is too painful and too uncertain; the simple ligature, or the double ligature with section of the artery between them, is very preferable; whether machure or torsion may ever rival them is at present improbable. If the artery be much diseased, the ligature cannot be applied, unless it be flat, or for the purpose of securing a bougie or other foreign substance within the arterial canal; the torsion not at all. What stand the operations I have advocated upon the sac may take, a long experience must decide.

TRAUMATIC ANEURISM.

Traumatic aneurism is a consequence of a wound inflicted upon an artery; the blood escapes into the surrounding tissue, where it is either circumscribed or diffused.

It is usually seen where the wound is small, deep, and irregular; the blood being unable to find its way out, infiltrates the tissues, or hollows out for itself a cavity; it may succeed to any other violence under which the arterial tunics give way, may succeed to the application of a ligature, which has ulcerated through the coats, before the artery is obliterated.

It is not always easy to distinguish this kind of aneurism; if it succeed to a wound made by a penetrating instrument, arterial blood at first escapes from the wound, or it may be at the same time a mixture of arterial and venous blood. Some movement changes the relation of the parts, or compression is made to prevent a further flow of blood, and then the blood passes freely into the adjoining cellular tissue, which it infiltrates to a greater or less distance. If it get to the subcutaneous cellular tissue, the skin presents a mottled appearance. This infiltration may very rapidly produce tumefaction, or it may proceed so gradually and insidiously as to lull suspicion for many days. When an artery or a large aneurismal tumor

has given way without external wound, the tumefaction may come on very quickly, and the pain may be very great; if we press strongly upon it, obscure pulsation is sometimes discovered, but usually all we discover is a thrill opposite the opening of the artery.

The distension consequent upon this kind of infiltration may be very great, the tissues may even be strangulated, the blood may break down and undergo putrid decomposition, under the influence of which suppurative or gangrenous inflammation may be developed. The limb becomes insensible, is covered with vesicles filled with fetid serum, and the patient dies either exhausted with hemorrhage or mortification. But, instead of that, the opening in the vessel may be blocked up, and the coagula may be absorbed. In some cases, instead of freely infiltrating surrounding tissues, those tissues are condensed around the extravasated blood, and constitute for it a sac or cyst communicating with the artery, and in many respects resembling the sac formed by the external tunic of the artery in what is termed true aneurism.

When we examine one of these circumscribed aneurisms, we usually find on one side of the tumor the cicatrix of the wound which penetrated to the artery; we see that the cyst is cellular, but generally thinner than in true aneurism. In its interior we find a single mass of coagulum and a small quantity of fluid blood, sometimes concentric layers of reddish fibrinous clots; the more dense externally, the more soft internally. When we remove the clots, we discover the opening in the artery sometimes oval, sometimes rounded; it is usually found on the side of the artery, corresponding with the wound of the integuments.

Prognosis.—Traumatic aneurism is as much more serious as the wounded artery is nearer the trunk, deep seated; that much blood is extravasated; and that it threatens decomposition. When it is circumscribed, *ceteris paribus*, it is a less serious disease than true aneurism; the tumor increases more slowly; it is more frequently cured by compression; and if operation be necessary, there is more chance of a healthy artery for the ligature: besides that, there is less chance of the development of the disease in another point. But when traumatic aneurism results from the wound of a large artery, it is a very serious disease; infiltration proceeds rapidly, and the distension is extreme. The danger is less when the artery is smaller; but even then, if it be deep, it is very serious. Generally, in these cases, the resources for carrying on the circulation after obliteration are lessened.

Treatment.—In many cases of traumatic aneurism, compression applied upon the

tumor will completely succeed. I have known three cases in which, in the act of bleeding, the artery was punctured at the bend of the arm, and all bad symptoms were prevented by graduated compression; but as a general rule, if the artery be deep seated, pressure upon the part cannot prudently be made. If the disease make no progress, it should be let alone. If the disease be not restrained by compression, or if it cannot be conveniently borne, then we must have recourse to the ligature: but an interesting question arises here—where is it to be placed? When the situation is favourable, many surgeons insist on the necessity of fairly exposing the wound of the artery, and applying ligatures above and below it. Guthrie strongly advocates this plan, even when the artery is deep-seated. Delpech objected to this course, and maintained that a ligature between the wound and the heart was the proper course to be followed; so did Dupuytren. The point has been much discussed, and the result seems to be, that in the first few days a single ligature will do, unless there be enormous anastomoses. When, on the contrary, a sac is fairly formed, and hæmorrhage has occurred from the wound several times, this method *may* succeed, but the chances of secondary hæmorrhage are increased. My own opinion is, that where the artery is superficial, and easily got at, the two ligatures ought to be applied; but where considerable difficulties are likely to be experienced in exposing the artery, it is wise to tie at a little distance from it; where most facilities will be afforded. There are many men who maintain that the chance of hæmorrhage from the furthest extremity of the artery is greatest. They, of course, condemn the Hunterian operation; but I still adhere to the opinion, that it is better to try the effect of tying at a distance than to cut down through a large bed of muscles—as in a large calf of the leg, to get at the posterior tibial; or the ulnar artery in the upper third of its course.

VARICOSE ANEURISM.

A varicose aneurism is a tumor produced by the passage of arterial blood into a vein: this may be a consequence of a wound, or disease. In 1757, Hunter described this disease. Guattani afterwards described it in a memoir, "*De spurio brachii aneurysmate.*" It is at the bend of the arm that we usually see this species of aneurism, and as a consequence of bleeding; the lancet passing through the median basilic vein into the artery which, in many cases, is immediately under it (see fig. 1). It may be produced elsewhere, has followed a sword wound and gun-shot in the ham, a puncture of an awl in the upper part of the thigh, and may, of

FIG. 2.

course, occur wherever an artery and vein are near each other. In all the cases which I know, except two, there was an external wound to explain how the communication between the two vessels had been established. One of these cases was observed by Professor Syme; the communication existed between the aorta and the inferior cava; the other occurred in the practice of Mr. Perry, at the St. Marylebone Infirmary; the communication was between the femoral artery and vein. In these two cases there was no external wound to account for the condition, and we must therefore assume that an abscess may have been developed in the cellular tissue between or in the coats of one of these vessels, and that by this means the communication was established with the other.

Symptoms.—However developed, an ovoid tumor is more or less rapidly developed in the course of the artery and vein; it pulsates, and the impulse is isochronous with the pulse. It is a more tremulous sensation than that observed in ordinary aneurismal tumors; the veins around are dilated. The tumor disappears more or less completely under pressure, or when we compress the artery above it, or if we press circularly above and below the tumor. When the disease has existed some time, and the tumor is large, the artery above the point becomes dilated, and sometimes flexuous. In the arm, the ordinary effects of this disease are to produce numbness below the tumor, a certain loss of muscular power, and some flying pains. It may remain long stationary: in Hunter's case, the man lived 35 years after the injury.

In the lower limbs the inconvenience is usually greater: besides pain, numbness, and muscular debility, there is a diminished temperature; and there may be great dilatation of the superficial veins, tumefaction, and often ulcers. All observers are agreed that the arterial blood passes into the vein. Breschet has endeavoured to prove that a certain quantity of venous blood passes into the artery: as proofs of this, he refers to the numbness, the sensation of cold, the loss of muscular power, and diminished sensibility; which he believes to be produced by the circulation of venous blood in the arterial system. He believes the introduction of venous blood to be intermittent; that during the systole of the artery, arterial blood passes into the vein, and that the venous blood passes into the artery during its period of dilatation. This, however, is doubtful.

Treatment.—Varicose aneurism may be cured by compression applied to the tumor; but it is a tedious, and often painful, mode of treatment, and should not be employed except in recent or superficial cases. If the disease appear stationary, we may adopt Clegborn's advice: recommend the patient to make little use of the affected limb, and carefully watch it. But it often happens that the inconvenience increases, and it may become so considerable as to require active treatment. Some surgeons attempted to cure the disease by tying the artery above the tumor, but they almost universally failed, as might have been expected, because there is no analogy between ordinary and varicose aneurism; and therefore the same treatment was not likely to succeed. When the artery is so tied, the collateral circulation soon brings the blood to the opening, and it passes into the vein. Guthrie has shewn the imprudence of employing this method. The only proper mode of treating this disease is, failing compression, to treat it as we should a wounded artery—cut down upon it, expose the wounded point, and tie the artery above and below it.

In a few words, I will seek to put you in possession of the distinctions which pathologists have pointed out in aneurism. I have avoided them till now: I feared they would serve to complicate the subject, and render it less intelligible. I believe that *true* aneurism, in which the whole of the arterial tunics are entire, is frequent; I believe that a *single* specimen exists of that species of aneurism, described by Haller as "*aneurysma herniam arteriæ sistens*:" it consists of a dilatation of the internal tunie, and of its passage through an opening in the middle tunie. The specimen to which I refer was presented to the Society of the Faculty of Medicine of Paris, by Dubois and Dupuy-

tren. I know that false aneurism, where one or more tunics have given way, is by far the more frequent; that traumatic aneurism is much less frequently seen—not much more frequently, indeed, than varicose aneurism. A distinction is made between varicose aneurism and aneurismal varix; the first being formed by the immediate passage of the blood out of the artery into a vein; whilst, in the second, the blood is at first effused into the cellular tissue, forms a sac, and afterwards penetrates into a vein, as in the diagram. But this is very unfrequent.

Again, you will see described *primitive false aneurism*, and *consecutive false aneurism*. In the first, the blood passes at once into the cellular tissue, which it infiltrates; in the second, a clot fills up the opening into the artery, and prevents the blood from passing out: ultimately the plug may give way, and a certain quantity of blood passes out, and a cyst is formed around it. These distinctions are of a certain value in practice, but that value has been already indicated.

BETHLEM HOSPITAL.

Report of the Commissioners concerning Charities.

REPORT BY MR. MARTIN.

THE House of Bethlem was originally founded as a convent by Simon Fitzmary, a citizen of London, who, by deed-poll, dated in the year 1247, granted unto the church of St. Mary of Bethlem all his land in the parish of St. Botolph Without Bishopsgate, to be held in frankalmoin for the foundation of a priory; the prior, canons, brethren, and also sisters of which were to profess the rule and order of the church of Bethlem, bearing the sign of a star publicly in their caps and mantles.

No satisfactory information has been obtained respecting the manner or period of the conversion of the convent into a hospital; but Stow states that it was said that a king of England caused a number of distraught and lunatic people, who before were maintained in a house near the parish church of St. Martin in the Fields, not liking such a kind of people to remain so near his palace, to be removed farther off to Bethlem Without Bishopsgate. In the year 1330, the house had acquired the name of "a Hospital," and is so described in a license granted by Edward III. to the master and brethren to

collect alms; and in the Harleian MS. there is a copy of a letter of the same date from the Archbishop of Canterbury, granting indulgence, to all who had contributed to the support of the Hospital of Bethlem.

In 1346, an application was made by the master and brethren, to the mayor, aldermen, and citizens of London, to be received under their protection. It was proposed that the house should be governed by two aldermen, one named annually by the mayor and aldermen, the other by the master and brethren; and to this assent was given. From this document it may be collected that the monastery fell into decay shortly after its foundation, and that the brethren of the house were dispersed abroad in the collection of alms.

By an ancient entry in the muniment-book of the hospital, it appears that, in 1375, it was seized into the hands of the crown as an alien priory; and it was certified that it was of the foundation of the City of London, and was worth, by the year, six mares. During the reign of Richard II., the right of presentation to the mastership of the hospital became a matter of dispute between the citizens and the crown, and, in 1389, the question appears to have been referred to Chancery. At this time the hospital still retained the character of a religious house; for the Lord Bassett, in one will, gave 200*l.* for the foundation of four chantries, two of which were to be at Bethlem, and, in another, gave to "the Hospital of our Lady of Bethlem Without Bishopsgate," 200 mares.

The earliest mention that has been found of the reception of lunatics in Bethlem is in a visitation of the hospital, made by virtue of a royal commission in the 4th year of Henry IV. The record of the commissioners states that, of the master, brethren, and others of the original foundation, there was now only a master, who did not wear the "prescribed dress;" and it also mentions that there were then in the house six men deprived of reason, and three other sick: it mentions also six chains with their appurtenances, with locks and keys, and four pairs of manacles of iron, and five other chains of iron, and two pairs of stocks.

In the year 1546, the hospital was bought by the citizens for the sum of 113*l.* 6*s.* 8*d.*, and, after remaining in the charge of the chamberlain and others for some years, it was placed, in 1555, under the care of the governors of Christ's Hospital. In 1557, at a general court of the governors of all the Royal Hospitals, Bethlem was placed under the management of the governors of Bridewell; and the union still subsists, having been confirmed by the Act 22 George III. c. 77, by which the present constitution of the Royal Hospitals was sanctioned and established.

The present government of the two hospitals is vested in a president and a treasurer, the court of aldermen, twelve common councilmen, elected in the same manner as the similar governors of St. Bartholomew's and St. Thomas's Hospitals, and an unlimited number of nomination governors, who are eligible on the payment of 100*l.*, or, if nominated by a steward of the annual dinner, 50*l.* The president has also the right to nominate two governors annually; and the treasurer one annually, who then become governors without ballot or benefaction. The present number of governors is 343.

In the year 1555, the possessions of the hospital amounted to 43*l.* 8*s.* 4*d.* yearly. In 1632, its estates would, if out of lease, have produced about 470*l.* per annum. For many years after this period its resources were inadequate to the maintenance of the patients; and it is mentioned that, in 1642, the Easter preachers at the Spittle were requested to plead its necessities. Forty-four lunatics, at least, were at this time continually kept with food and physic.

The present possessions of the hospital consist chiefly of houses in and near Liverpool-street, which formed part of the property of the original grant from Simon Fitzmary, and are now worth upwards of 1200*l.* a year; houses in and about Piccadilly, obtained by exchange with the crown for houses required to be pulled down for the improvements at Charing Cross; houses in various other parts of the city; an estate at and about Wainfleet, in Lincolnshire, and upwards of 100,000*l.* stock. The gross annual income, taken on an average of ten years, ending Christmas, 1836, was as follows:—

Curable Fund.

Rents and annuities	£5881	5	1
Dividends	2834	7	2
Legacies and benefactions	405	15	9
Payments on account of patients	144	18	6
		9266	6 6

Incurable Fund.

Rents, annuities, and dividends	£5688	9	7
Legacies and benefactions	28	18	11
Payments on account of patients	1279	19	8
		6997	8 2
		£16,263	14 6

In 1642, it appears that the house could not maintain more than fifty or sixty patients, and these with but poor accommodation. In 1676 it was rebuilt, after the great fire, and was made large enough to contain upwards of 120 patients, and two wings were added to it in 1733, for the reception of incurable patients; it was also further enlarged in 1793. But from having been constructed in great haste, it was found that in 1799 all the buildings of the Old Bethlem Hospital were in a very bad condition, and in 1807 it was determined to effect an exchange of property with the corporation, for eleven acres of land in St. George's Fields, on part of which the present hospital, which was to be large enough to contain 200 patients, now stands. An Act of Parliament was obtained, in 1810, for erecting the said hospital, and upwards of 122,000*l.* being obtained from various sources, including upwards of 70,000*l.* granted by parliament, 3000*l.* from the corporation, and upwards of 23,000*l.* from the hospital funds, the building was completed in 1815.

Former treatment of the patients.—It seems probable, that from the first reception of lunatics into Bethlem, their condition and treatment were wretched in the extreme. The iron chains, with locks and keys, mentioned in 1403, and the manacles and stocks then spoken of, indicate but too plainly the system then pursued. In 1598, a committee, deputed to view the house, reported that it was so loathsome, and so filthily kept, that it was not fit for any man to enter. It contained no more than twenty inmates, who were termed prisoners; and of these, six only were maintained at the expense of the charity.

Stow, however, says, that in his time there was "undoubtedly the greatest provision made for the patients of any public charity in the world; each having a convenient room and apartment for themselves, where they are locked up on nights, and in it a place for a bed, or if they are so senseless as not fit to make use of one, they are every day provided with fresh and clean straw." And after mentioning other advantages of airing, bathing, and excellence of diet, he speaks of the care that was taken of their other illnesses besides lunacy, and marvellous cures of many fearful diseases; and concludes, "so that by God's blessing, for twenty years past, ending 1703, there have been above two patients in three cured, as the physician hath told me." The number of patients at this time was seldom less than 136; and the hospital was with these always crowded and full.

Amongst the conflicting accounts which are next given in the report, from the evidence taken before the House of Com-

mons in 1815, and from the reports of the Committee of Management, it might be difficult to determine whether up to that time any change in the management of the patients had been made in the direction of improvement. The degree of restraint to which many of them were subjected, was clearly in many cases unnecessary, and in all unjustifiably severe. In 1816, in consequence of the strict investigations that were then just completed, the physician and the apothecary were not as usual re-elected; and it was resolved that no patient should be kept in constant restraint for more than eight days, without a consultation of physicians on his case, and their sanction in writing for the continuance of such treatment.

Present management of the hospital.—The patients are of two classes; those admitted for cure, and those who have been discharged as incurable, and are afterwards received on the incurable foundation. Inadmissible cases are those of lunatics who are possessed of property sufficient for their decent support in a private asylum. 2. Those who have been insane for more than twelve months*. 3. Those who have been discharged from any other similar hospital. 4. Female lunatics who are with child. 5. Lunatics in a state of idiocy, or afflicted with palsy, epilepsy, or convulsive fits. 6. Lunatics having syphilis or the itch. 7. Those who are blind, or so weakened by age as to require the attendance of a nurse, or to threaten the speedy dissolution of life, or who are so lame as to require the assistance of a crutch or a wooden leg.

All who are not thus disqualified are admitted at all seasons of the year, and provided with every thing necessary for their complete recovery, if the same can be effected within twelve months. They are admitted on the presentation of a petition, signed by some near relation or friend of the lunatic, together with a certificate of its truth, signed by the minister and parish officers of his parish, and a certificate of lunacy signed by the medical attendant. The petitions are considered by the governors on the Friday following their presentation, and, if judged a fair subject for admission, the patient is desired to be brought for examination by the physicians of the hospital, at 10 A.M. on the following Friday. In cases of urgent recent insanity, admission is given on the first Friday, and extraordinary cases are received at any time, by order of the committee, president, or treasurer. Before a lunatic can be admitted, two respectable housekeepers must attend at the hospital, and enter into a bond of 100*l.* to take him or

* This restriction is not acted upon when there is a fair prospect of cure.

her away whenever the committee shall think proper to direct, and to pay the expense of burial if the patient die in the hospital.

The patient being brought to the hospital at the time appointed, is examined by the physician in attendance, and the particulars of his case are taken down in writing, and a report made to the sub-committee, who at once send those who are deemed fit objects to the galleries. In 1836, 311 petitions were presented; of which 273 were approved, 28 postponed, 8 rejected; of the 273 whose petitions were approved, 253 were admitted after examination; the rest being found idiotic, or paralytic, or otherwise disqualified.

The curable patients are distributed in three classes: the basement gallery is expressly for the furious and mischievous, and those who have no regard to cleanliness; the first floor is intended for ordinary patients on their admission, and for those who are promoted from the basement; the second floor is for patients who are most advanced towards recovery; the remaining galleries are appropriated to incurables. Patients, however, are often for various reasons changed from one gallery to another.

The apothecary resides in the house, and visits the galleries daily. The physicians attend, one on Wednesdays and Saturdays, at one; the other on Mondays and Thursdays at ten, and at other times when their advice and assistance are required. The patients are nearly equally divided between the two. All the curable patients, and the criminals, and in general the incurables, are seen by their physicians at least twice in each week. Aperient medicine (cal. gr. iij. rhubarb, gr. xvii.) is usually given on admission, unless contrary directions are received from the physician.

The patients of both sexes who are capable of employment are set to work as soon as possible about the ordinary business of the house, in assisting the nurses and keepers in making the beds, washing and cleaning. The men pump all the water required for the use of the house, and some employ themselves in knitting, tailoring, and mending clothes. The females also, who are capable, are employed in the laundry, and in making up linen for the use of the hospital, and they do the ordinary needle-work for the hospital.

In the airing ground, some of the men play at ball, leap-frog, and other games; they also amuse themselves with cards and dominoes: and the women are encouraged to dance in the evenings: no regular handicraft occupations have been introduced.

Books also have been provided (in all 62 volumes), with the sanction of the physicians and chaplain. The females formerly

had a barrel-organ, but it has long been out of order; it is thought that music might be introduced into the house with advantage.

The following hours are observed throughout the house: the patients rise in summer at 6, and in winter at 7; breakfast at 8; dinner at 1; tea at 5; ordinary bed-time at 8. When the patients retire to bed, they are locked into their rooms, and the clothes of all of them are in general removed; when this is concluded each keeper on the men's side makes a personal report of it to the steward, stating the condition of the patients under his care.*

Every possible endeavour is made to dispense with personal coercion: the rules of the hospital forbid the restraint or confinement of any patient without the sanction of the physician or apothecary, leaving, however, a discretion to the matron, on condition that she report each case of restraint and of release from coercion to the apothecary. In practice, however, the keepers and nurses frequently coerce patients when they consider it necessary for their own safety, and that of the other lunatics, but the matter is instantly reported to the proper officer. Every case of restraint, however trifling, is required to be noted down and returned in each week to the committee. Chairs, to which proper conveniences are affixed, are occasionally used in the female side, the sides and backs being stuffed to prevent the patients from injuring themselves, and a moveable board or table placed in front, is locked on to the frame: violent patients are sometimes confined to their beds by iron chains, and rings affixed to the wall. The number of these cases is very small; none are reported in 1836, except among the criminals: during that year, 53 patients altogether were subjected to restraint; and of these, 25 were reported only once, and 16 twice. The most usual means employed are the belt and gloves, or the belt and wrist locks, on one or both hands; restraint is never used till the patients are actually violent, unless when suicide is feared. The keepers have often been seriously injured; but the matron, in the course of her duty during twenty years, has never received the slightest violence, nor even been threatened with a blow.

Those patients who are capable are required to wash and comb themselves daily, and the others are washed and combed by their attendants; the dirty patients are cleaned whenever occasion requires it: men are shaved twice a week by the keepers. Those patients whom it is

* A part of the management of the patients is illustrated by references to the plans of the buildings. Without the engravings of these, this portion could not be intelligible, and being by no means highly important it is here omitted.

necessary to confine to their rooms, are shifted every two or three days to a different room, in order that every article of furniture about them may be thoroughly purified, and the room whitewashed. Much attention is paid to the apparel of the patients, particularly with a view to the warmth of the extremities: the clothing not being supplied by the charity, all articles furnished from the hospital stores are repaid by the patients' sureties. The sums charged by the hospital for the clothing of curable patients during eight years, have amounted on an average to less than £1. per annum for each person.

The bedding is furnished by the hospital: the violent and raving mad patients do not use sheets, but lie between blankets upon loose straw, which is shifted daily; the destruction of blankets is exceedingly great.

The patients who are thought by the physician to be sufficiently composed, are permitted to attend chapel, where an abridged service is performed on Sundays, and a short address adapted to their condition is delivered by the chaplain: permission to attend is much prized, and is attended with a very beneficial operation, and is considered as a step towards convalescence; the indiscriminate use of bibles and prayer-books is not allowed. The chaplain visits the patients in the galleries who require his attendance, under the sanction of the physicians. Roman Catholic priests also are admitted in the same way, to all who seek their assistance; but persons who profess wild or fanatic doctrines would not be permitted to enter: prayers are read in the chapel on Tuesdays and Thursdays; but the attendance is much smaller than on Sundays.

The friends of patients are admitted to see them on the first and third Mondays of the month, subject, however, to the approbation of the medical officer; they are required to write their names and address in the porter's book in the hall: the average number thus admitted is thirty-nine each time: they are as far as possible prevented from bringing anything deleterious. All letters written to patients are read by the matron, or the steward, or apothecary, and if necessary, withheld for a time: letters also are not sent from patients without sanction.

The patients are in general healthy in body. Typhus fever is of very rare occurrence, and no case of cholera occurred during its prevalence in London, great precautions having been taken to prevent it: a change was made in the diet of the patients, meat being served to them daily, and rice substituted for the ordinary vegetables. In 1836-7, the house was severely visited by the influenza; and almost every patient who died before June, 1837, was

found, on examination, to be diseased in the lungs. The post mortem examinations are made by the surgeon, and all the particulars are recorded in his case-book.

Patients, whose cure is effected within the year, attend to return thanks to the governors, or are not afterwards again admissible: those whose cure is not so soon completed are permitted to remain, if there be hope of ultimate recovery; if there be no such hope, they are brought before the committee, and discharged as uncured. A report is made by the physician of such among them as are fit to be received in the incurable foundation; and, if thought proper objects, their names are placed upon a list kept for that purpose, and notice given to the friends of each patient, in regular rotation, as vacancies occur. Persons whose disorder consists of mere incompetency, and who are neither violent nor dangerous, are not considered fit objects for this branch of the charity; and the blind, lame, and epileptic, are also excluded. The incurable list is at present restricted to 25 men, and 10 women. They are not entirely maintained at the expense of the charity, a small weekly charge being made for their maintenance.

The criminal lunatics are treated in precisely the same manner as the others. Some few of them are occasionally cured.

Taking the average of the ten years from 1827 to 1836 inclusive, the numbers of patients, both male and female, and the terminations of their cases, are as follows:—

CURABLES.

On the books, January 1st	114
Admitted in the year	203
Total number on the list for the year	317
Discharged cured.....	104
Out on leave, (average of four years),	19
Discharged, as being improper objects	30
Discharged, at request of friends.....	3
Discharged uncured... ..	50
Deaths	9.5
Number discharged cured, out of each hundred admitted	51*

INCURABLES.

Remaining in the house, Jan. 1st.....	64
Admitted in the year... ..	5
Discharged cured in ten years.....	6
Died, average	2.9
Mean duration of stay of each incurable patient, 12 years and 210 days.	

CRIMINAL LUNATICS.

Remaining in the house, Jan. 1st....	57
Admitted in the year.....	2.7
Cured.....	1.6
Escaped, two in ten years.	
Died.....	1.6

* If the cases stated to be out on leave in the returns of four years, be included among the cures, as they are in the other years, the proportion of cures to admissions will be, on an average of ten years, 55 per cent.

The total average expense per annum of a curable patient to the charity, in 1836, was.....£41 5 4
 Ditto, ditto, to his friends..... 0 14 11

Total average expense per ann. £42 0 3

Average expense of an incurable patient to the charity in the same year...£21 0 10
 To his friends 20 19 6

Total..... £42 0 4

Average cost, per annum, of a criminal lunatic, about.....£36 0 0

Average payment, per annum, for each to the hospital..... 45 0 0

Average gain to the hospital....£9 0 0

The following table of the patients in the hospital in 1836, may probably be taken as an average:—

Admitted.	Duration of Insanity previous to admission.	Cured.
1	Not exceeding 18 months.	
2	12 "	
8	" " 10 "	1
1	" " 9 "	1
7	" " 8 "	1
9	" " 7 "	1
14	" " 6 "	2
7	" " 5 "	1
14	" " 4 "	8
28	" " 3 "	18
37	" " 2 "	17
3	" " 1½ "	6
5	" " 1¼ "	4
44	" " 1 "	29
24	" " ¾ "	15
39	" " ½ "	24
10	" " 1 "	6
253		134

The average duration of insanity in the patients who were discharged cured was 56 days.

An abstract of the physician's annual reports, from 1820 to 1836, shows, that there were admitted in that period:—

	Curables.	Incur.	Crim.
	3090	97	67
Of whom were discharged cured	1480	22	32
Uncured	829	3	2
By request of friends	75	23	0
Improper objects....	483	6	0
No reports received of	14	0	0
Escaped.....	0	0	3
Died	145	47	28

The causes of dismissal of patients as improper objects, for six years ending 1836, were,

Paralytic.....	87
Sick and weak	59
Idiotic.....	28
Epileptic.....	24
Apoplectic	4
Pregnant.....	3
Fits	2
Venereal.....	2
Aged and infirm....	1

210

The causes of death during the same six years were,—

Exhaustion....	23
Apoplexy	7
Epilepsy	6
Diarrhœa	6
Gradual decay	4
Bronchitis	3
Abscess of lungs	2
Hydrothorax	2
Suicide	2
Effusion of serum, syncope, consumption, chorea, peritonitis, debility, paralysis, and unknown cause, each one	8
	63

The report is concluded by drawing comparisons between several parts of the system of management of the patients in Bethlem, with that adopted at other lunatic asylums, and especially those of Hanwell, St. Luke's, Lincoln, Glasgow, Nottingham, and Wakefield; and in all cases to the disadvantage of Bethlem. It is submitted, that though to a casual visitor its perfect cleanliness, and the neatness of appearance and absence of all apparent restraint of the patients, might lead him to conclude that the management of lunatics has here attained perfection, yet there is still room for considerable improvement. Some of the defects in the present arrangement are, no doubt, to be attributed to the construction of the building, which appears to have been erected partly on the plan of the old hospital in Moorfields, with a view to the continuance of the coercive system there pursued, and is by no means well adapted to the present improved method of treatment. The aspect, it is said, is not good, the gallery windows facing to the north: the windows are too high from the floor, formerly more than six feet; the lower galleries ought not to be on a level with the earth, nor is there any necessity for stone floors in them. The centre of the building is obscured and made gloomy by a heavy useless portico, and the back is even more gloomy and repulsive than the front. The gloomy exterior of the hospital, and the heavy unsightly window-bars, savour strongly of the times of rigour and coercion; they are

compared with great disadvantage with those in the lunatic asylums at Lincoln and at Nottingham, which are like common windows to external appearance, but are secured from being opened more than a certain distance. It is considered as much to be regretted, that the governors should have consented to the erection of the wings for criminal patients, by which the patients were deprived of the space now devoted to the use of objects who could not have been in the contemplation of the citizens when the existing lease was granted. The criminals now enjoy a larger quantity of ground in proportion to their numbers than the ordinary patients. The whole of the land held by the hospital appears no more than sufficient for the wants of the patients, but a very small portion only is devoted to their use. The kitchen gardens and the two lawns might be at once used or made fit for use as airing grounds, and the present airing grounds, which are mere bare cheerless inclosures, might be planted and rendered far more agreeable than at present.

Within the house the most striking feature is the want of occupation for the men, the greater number of whom may be seen sauntering about the galleries in listless and hopeless indifference. Some, indeed, play in the airing grounds, and a few are occasionally employed in the lawns and gardens, or in knitting; but the only general occupation is that of pumping at the crank and capstan. At Wakefield, Nottingham, Hanwell, Glasgow, and many other places, on the contrary, the occupations are of the most varied kinds, and the patients are even taught trades with which they were before unacquainted, and are employed as blacksmiths, weavers, shoe-makers, carpenters, tailors, &c. The intellectual employment also of the patients at Bethlem appears capable of great improvement: only a very small portion of them occupy themselves in reading, and it was stated by the matron that the women do not in fact enjoy the use of the library. Personal restraint also, though so much less than formerly, is still considerably greater and more frequently employed than in many other asylums.

Other suggestions for improvement relate to the too great caution which is evidently displayed before the patients, in every thing around them being distinctly adapted to prevent them from harming themselves or others; the absence of any medical school or system of pupillage, by which medical science might be advanced, at the same time that it would (as it does in the general hospitals) afford a constant stimulus to the exertions of the medical officers; the propriety of having a resident

physician, with suitable assistants and a remunerating salary, or of making an increase in the number of physicians, and, perhaps, an addition of one or two ordinary practitioners to those who devote themselves chiefly to the cure of insanity; the necessity of a greater portion of statistical information being afforded by the annual reports; the propriety of relaxing some of the restrictions by which certain classes are at present disqualified from admission, as those against persons with venereal disease or itch; and the importance of shortening the period between the consideration of the petition and the admission of the patient. The remaining strictures upon the hospital relate to the financial department both of itself and Bridewell, (with which it is urged its union is no longer reasonable), and they are made with a degree of severity which is entirely absent in the corresponding remarks on the other hospitals.

FATAL CASES

OF

OBSTRUCTION AND ENORMOUS DISTENSION OF THE BELLY,

Arising from a peculiar Conformation of the Colon.

BY ANDREW BUCHANAN, M.D.

Professor of the Institutes of Medicine in the University of Glasgow.

(With 12 Figures in illustration.)

[Concluded from p. 105.]

THE three cases which I have just narrated exhibit many striking points of resemblance. In all of them the most remarkable symptom was the extreme distension of the abdomen. So great was this distension, as to communicate, both to the unhappy sufferers themselves and to the bystanders, an apprehension of the actual bursting of the belly. On opening the cavity after death, the inflated bowels were propelled with such force through the wound, as rendered extreme caution necessary to avoid injuring them; and on puncturing the bowels themselves, the imprisoned gases rushed forth like the winds from the cave of Æolus, or, to speak a little more plainly, with a violence that would have extinguished a candle held at some distance from the aperture. To those who have not seen this complaint, I cannot convey a more accurate idea of it than by comparing it to the disease which occurs in cattle after eating too

much wet clover or othersucculent herbaceous food. I have seen several cows affected with this complaint, and in none of them was the swelling greater than in the cases described above.

The next most remarkable circumstance attending these cases was the total obstruction of the bowels; to overcome which the most powerful purgative medicines introduced into the stomach, and all clysters and suppositories, were quite ineffectual. At the same time, the facility with which clysters could be injected into the rectum, as well as the examination of that intestine with the finger, showed the cause of the obstruction to be at some distance from the external orifice.

Another circumstance worthy of remark is, that in all these cases, previous to the occurrence of complete obstruction, the bowels had been long affected with constipation. This was rendered obvious, independently of the report of the patients, by the accumulation of fæces in the bowels, which was so very large, that it must have been a long time in collecting. The same point was still further evinced by the extreme dilatation of the colon, which shewed clearly the existence of a dilating cause, which had been in operation most probably for years before the death of the patient. The fully inflated colon, in its normal state, I have found to be about two and a half inches in diameter; now in the case above mentioned, it was from five to six inches in diameter; that is, it contained at least four times as much fæces as when quite full in its ordinary state. It was the large intestine alone that was thus dilated; for the small intestines, although fully inflated, were not wider than natural.

Death took place in about twelve or fourteen days from the occurrence of the total obstruction of the bowels. The disease must therefore be regarded as an acute one; and this enables us to distinguish it from certain chronic affections, attended with swelling of the belly and obstruction of the bowels. To what cause is death to be ascribed in such cases? The mere obstruction of the bowels cannot be considered as an adequate cause, since men have been known to live for more than a quarter of a year without any alvine evacuation. Neither was the cause inflammation of the bowels; for although inflammation

had obviously been going on in one of the cases mentioned above, it must have been a mere accessory, since there was no inflammation in the other two cases. Can the elevation and immobility of the diaphragm, and the encroachment of the abdominal viscera upon the cavity of the heart and lungs, be regarded as the cause of death? It may probably be an accessory cause; but I am disposed to think that the principal cause of the patient's death is the excessive distension of the belly, which produces the most excruciating and unremitting pain, and thus gradually exhausts the powers of life. In the analogous disease of cattle, already mentioned, death seems to proceed from the same cause; but it takes place in them much more rapidly—generally in the course of a few hours—owing to the distension being much more sudden, and acting upon tissues not previously habituated to that kind of irritation.

The symptoms enumerated above—the enormous tympanitic swelling of the belly, the complete obstruction of the bowels, the emptiness and large size of the rectum, and the acute course which the disease observes—appear to me to be sufficiently characteristic to enable us to distinguish this disease from all other kinds of tympanitic swelling and constipation.

With respect to the appearances on dissection, in all the cases the colon was the organ principally, and, as was universally thought, primarily affected. It was much longer than usual, and occupied an unwonted situation, lying in front of the small bowels; it was also much enlarged, having an area four times larger than when fully distended in its ordinary condition. These appearances are partly to be referred to primordially confirmation, and partly to the long-continued action of a distending cause. That the great length and unusual disposition of the sigmoid flexure must be referred to primordially conformation cannot, I think, be doubted. On the other hand, the great width of the intestine must have been gradually produced, and could not proceed from original formation, as was obvious from the attenuation of its coats and other appearances. Before I was aware that the length of the intestine varied from original confirmation, I laboured to persuade myself that the elongation of the colon, as well as its dilatation,

FIG. 7.—Morgagni.

FIG. 9.—Drs. Hunter and Buchanan.

FIG. 12.—Dr. Buchanan.

might be the effect of long-continued tension. How easily we impose upon ourselves by such reasoning will be seen from a case quoted below, in which the colon, from original formation, was shorter than usual; and the narrator, to explain the difficulty, argues that an increase of width must be necessarily attended with a diminution of length.

In the two cases last narrated, a twist of the colon was supposed to be the cause of the obstruction of the bowels; and this opinion accords with that entertained of all the other cases of this disease which I have found on record. Nevertheless, I much doubt the accuracy of this opinion. When we remove the intestines, to examine them out of the body, we find them very apt to become twisted, knotted, and otherwise variously entangled. Nothing so well illustrates the wisdom of the provision by which such accidents are prevented from taking place within the body. By a twist of the intestine may either be meant, that a single ply of the intestine is twisted round its own axis, or that an angle of the intestine is twisted—that is, that two conterminous plies are twisted round each other. This last kind of twist will be adverted to in reference to a case quoted below. It is certainly possible, but we cannot easily conceive a force acting within the body capable of producing it, and maintaining it when produced. The other kind of twist is that supposed to have existed in all the other cases. I cannot, however, see how it is possible, without an opening in the mesocolon large enough to admit of the intestine revolving on its axis, to produce such a twist as would cause obstruction of the bowels. I can conceive it possible that a violent and irregular action of the muscular fibres could produce a twist, half round, of a particular portion of the intestine; by which I mean, such an oblique folding of that part of the intestine, that a given point of its circumference would be carried from the side on which it naturally lay to the side diametrically opposite; but I cannot conceive the production of a complete twist of the intestine, by which I mean, a point of the circumference being carried first to the opposite side, and then completely round to the situation from which it originally set out. I can conceive no force, acting within the body, capable of producing such an effect; and, waiving the ques-

tion of the existence of an adequate force, I believe the effect to be physically impossible without rupture of the mesocolon. Still further, any twist depending upon irregular action of the muscular fibres could not, as appears to me, be maintained for so long a period as twelve or fourteen days, and still less for whole months. Now I have shown that, in the preceding cases, the bowels bore marks of having been for a long time in a state of obstruction, although it was only when that obstruction became complete that the disease here under consideration was developed.

In the history of the case first narrated, I have described in what way the proximal convolution of the sigmoid flexure passed in front of and compressed the extremity of the colon, a little above where it terminates in the rectum. Now when we consider the great length and unusual position of the colon in the other two cases, and in similar cases upon record, it appears to me not improbable that the same, or a similar cause of obstruction, may have existed in them also. There is one circumstance with respect to the course of the colon in case first, which may either be explained as proceeding from original confirmation, or from subsequent displacement; I mean the sweep to the right which the intestine took after leaving the left ileum, and before ascending to the epigastrium. That this disposition was not the effect of primordial conformation, it is impossible to say; but we might oppose to that opinion the analogy of two cases described above—that of Dr. Hunter, and that observed by myself at the Cholera Hospital—in which the intestine, immediately after leaving the ileum, passed obliquely to the upper region of the belly. If such was also the original conformation in case first, we must suppose that when the feces began to accumulate in the oblique portion of the colon, they carried it downward by their weight towards the pelvis, as appears to me would naturally take place.

In describing the two cases referred to at the beginning of this essay, I mentioned as a circumstance worthy of remark, that in both of them the colon entered the pelvis on the right side, instead of descending in the usual way over the promontory of the sacrum, and entering it in the centre. The end of the colon was thus removed as far as

possible out of the reach of the danger of being compressed, by the proximal portion of the sigmoid flexure passing in front of it. It seemed, therefore, as if nature, retaining in her vagaries the same provident spirit which distinguishes her more uniform operations, had foreseen the danger to life which the unusual formation of the colon would produce, and had taken steps to avert it.

I have been for many years past anxious to have an opportunity of dissecting a cow dead of over-distension of the belly. I entertain little doubt that, on examination, it will be found that the distension of the paunch and adjacent parts of the alimentary tube produces, by its pressure, a mechanical obstacle to the transmission of the excrementitious mass; or, more probably, prevents the act of regurgitation, which, in ruminating animals, is essential to digestion. This appears to me at least to be the most probable explanation of the confinement within the body of the animal—of the wind and excrement with which it is distended almost to bursting. Should this conjecture be verified, there will be a very close analogy between this disease of cattle and the disease of the human subject described above. In both it is the severe tympanitic distension of the belly that occasions death; and the chief difference between them appears to be, that while in cattle the tympany is produced by the sudden ingestion of flatulent substances into the stomach, in the human subject it is produced by the gradual accumulation of them in the colon.

From the account now given of this disease it must be obvious that, in treating it, all purgative medicines are useless, as well as all clysters administered in the ordinary way, so soon as the rectum has been emptied of *fæces*. The first and great object of our treatment should be to remove, if possible, the mechanical obstacle to the evacuation of the bowels. To facilitate this object the patient should be placed upon his hands and knees, or standing, with his body inclined forward, which has the effect of freeing the end of the colon from the weight of the first turn of the sigma lying over it. An instrument should now be introduced into the intestine, for the purpose of dilating the compressed portion. The instrument

for this purpose is the *œsophagus tube*, armed with a large sponge at the end. The sponge is easily fastened by means of a string attached to it, and passing through the tube; while, by means of the other half of the string running outside the tube, the sponge can be withdrawn when we wish to use the tube as an injecting instrument. In the first instance, however, we are to use it as a probe and dilator. After carrying it up as high as we may deem necessary, it is to be withdrawn, when, by examining whether or not the sponge be smeared with *fæces*, we can ascertain whether or not it has passed the compressed portion of the intestine. If it have passed, we should reintroduce it, and by passing and repassing it up and down through the compressed part, we should endeavour if possible to form a free passage, by making an indentation in the soft feculent sac, lying, in the position of the body here supposed, below it. Very probably we may succeed in this way in procuring a discharge of *fæces*, which without any contraction of the muscular fibres, would be protruded along the passage by the elastic force of the condensed air in the surrounding intestines. If we do not succeed, the tube must be again carried up as far as possible, and the sponge withdrawn, when we must inject tepid water or air, as may be found best to answer the purpose.

Suppose that we do not succeed in procuring any evacuation by these means, or that we succeed only partially, so that the tension remaining undiminished, it is still obvious that death must ensue, is the patient to be abandoned to his fate, or are there still other means of relief in our power? I answer without hesitation, that in the circumstances just supposed we should puncture the bowels. With what view should this operation be put into practice? Not certainly for the evacuation of *fæces*, which could not be prevented from escaping in part into the peritoneal cavity, and would so cause death. It should be performed, therefore, solely with the view of discharging air from the bowels, which will have the double effect of relieving the sufferings of the patient, and facilitating subsequent attempts to evacuate the *fæces* through the natural passages. In what situation should the puncture be made? This question reduces itself to the more simple one—in what part of the colon

should the puncture be made? for there is no other part of the intestine, in such cases, accessible to the puncture. The whole of the sigmoid flexure, and greater part of the left colon, containing only feces, are excluded from consideration, and the transverse colon is excluded by the uncertainty of its position. The right colon is the part of the intestine most uniform in its seat, and it is likewise distended almost entirely with air. I would therefore recommend puncturing the right colon, about the middle of its course, with a small trocar. On withdrawing the stilette, the confined air should be allowed fully to discharge itself, after which the attempts to evacuate the bowels may be renewed, probably with better success.

Still further to illustrate this disease, I subjoin the history of the only three examples of it which I have been able to find in the records of medicine.

The first occurs in the *Sepulchretum Anatomicum* of Bonetus—the father of pathological anatomy, and, we may therefore add, of rational medicine. It is extracted from the observations of Tidicæus, who flourished in the end of the sixteenth century; but not having access to the original work, I translate from the *Sepulchretum*, lib. iii. sect. xiii. p. 197:—

A pregnant female, during the whole period of gestation, and not less during the last month than before, was engaged in needle work without ceasing, from an early hour in the morning till late at night, constantly sitting, as it were, contracted and incurvated upon herself, with her head down, as is usual with those so occupied. Hence she became so costive, that she would have no movement for whole ten, fifteen, or even twenty days. This she esteeming of small consequence, neglected, persevering as long as she was able at her sedentary employment, until, on account of the incredible swelling and pain of her belly (both of which proceeded from the retention of the contents of the bowels), she was no longer able to sit at work. The unhappy woman at length takes to bed; the pain and swelling of the belly, and feeling of anxiety thence arising, increase daily, and to such an extent, that it was obvious to all who saw her that she was in a most dangerous condition. Suppositories and clysters, administered to move the bowels and alleviate pain, availed but

little; for whatever was the quantity or quality of the clyster administered, it only remained some time in the rectum (as afterwards appeared), soon coming away, and bringing nothing along with it. Labour at length came on, and the midwife being called, the fœtus, although immature, was nevertheless born alive. But notwithstanding the expulsion of the fœtus the belly did not in the least diminish in size, but was just the same, that I may not say greater; and the swelling, and resilience, and pain remained, so as to be terrible in appearance to the bystanders, who thought that the belly would burst on account of the excessive tension. It is needless to say more: the patient died, herself requesting that her belly should be opened after death and inspected, which was accordingly done.

The peritoneum being divided, and the omentum lifted up, the colon was the first object that presented itself, removed from its natural situation, and altogether gangrenous. Its colour was red, with a tinge of green (ex cæruleo rubricans), which colour also was visible through the abdominal muscles and skin, extenuated by over-distension. The intestine was distended with mere excrement, and of such a size as to resemble, in that respect, a jug, that would admit a boy's head. All the other higher intestines were, beyond measure, turgid with flatulence: hence the colon, at that part where it descends from the left kidney, had departed from its natural situation, as far as the region of the umbilicus, under which, situated between the tracts of the recti muscles, it was seen descending in the middle of the belly, in a straight line from the stomach. This arose partly from the pressure of the wind contained in the bowels behind it, and partly from the quantity of excrement in itself, which, extending the intestine laterally, rendered it shorter, or caused a contraction in point of length. Hence, without doubt, a twist of the lower part of the colon having taken place, where it is continuous with the rectum, the passage for the egress of feces and wind, and for the ingress of clysters, was completely shut up. On opening the colon, such a glut of fetid excrement flowed forth as if you had slain some beast of burden. And hence it is evident what may be brought upon pregnant women by a too sedentary mode of life and neglect of

the functions of the bowels, more especially in the last month of gestation.

It is worthy of remark, that the twist of the colon is here spoken of rather, apparently, as a deduction of reason than as a matter of observation. "*Hinc absque dubio ipsius coli . . . contorsione facta.*" To me it appears highly probable that the severity of this disease arose from the unusual position of the lower part of the colon. It lay in front of the small bowels, right in the middle of the belly, in which situation it must have been compressed between the inflated small bowels lying behind it, and the gravid uterus lying throughout its whole course in front of it. This is, therefore, obviously the same disease as before. The symptoms are graphically described, and coincide exactly with those observed in the preceding cases; and further, the disease originates in an abnormal formation of the lower end of the colon. It is, however, a variety of the disease, the colon being shorter than natural instead of being longer. Such a formation could not, so far as I can see, be dangerous but to pregnant females. The fact of the bowels being seen through the parietes of the belly is confirmed by a case given below.

The next case was observed by Dr. Abercrombie, of Edinburgh, in the year 1815, and is recorded by him in the sixteenth volume of the *Edinburgh Medical and Surgical Journal*, page 15.

A man, aged 60 (23d April, 1815), was affected with vomiting; pain in the abdomen, which was swelled and tympanitic; obstinate costiveness; pulse 108, and soft; countenance pale and exhausted; pain not increased by pressure. Had been ill a week, during which powerful remedies have been employed, without benefit. Had formerly two attacks of the same kind, one of which continued a week. This man lived in great distress till the 28th, without any remarkable change in his symptoms. The swelling of the abdomen increased gradually, until it resembled that of a woman at the most advanced period of pregnancy; yet, to the last, he could bear pressure upon every part of it. His pulse varied from 108 to 116. His death was sudden: he had been out of bed and dressed the day before, and, on the morning of the day on which he died, he did not appear worse than usual.

On opening the abdomen, a viscus came into view, which appeared to be the stomach, enlarged to three or four times its natural size. On a more accurate examination, this turned out to be the sigmoid flexure of the colon, in such a state of distension that it rose up into the region of the stomach, and filled half the abdomen. The stomach was contracted and healthy. The small intestine was healthy at the upper part; lower down it became distended, and of a dark colour; at the lower part it was very much distended, with some spots of gangrene. The colon was greatly distended—in some places it was not less than five or six inches in diameter—and terminated in the distended sigmoid flexure already mentioned. The rectum was healthy and collapsed. The sigmoid flexure was of a dark livid colour, and contained air and thin feces. What appeared to be the cause of this affection remains to be mentioned. The enlarged sigmoid flexure was found to have taken a remarkable turn upon itself, so that what was naturally the right side of it lay on the left, in contact with the descending colon, and the left or ascending part of it lay on the right. The consequence of this was, that the rectum as it descended from the former, passed down behind the lower or first turn of the sigmoid flexure, where it first takes the turn from the descending colon: also, the rectum itself, at this part received a twist, as if half round. Exactly at the point where this twist was, the distension and dark colour of the intestine terminated abruptly, and it became white and collapsed. At this part, however, there was no mechanical obstruction, for the parts were pervious, and, except the twist, perfectly healthy: and farther it happened, in this singular case, that I had an opportunity of ascertaining the state of them during life. On the 25th, three days before his death, having exhausted all the ordinary means, I was induced to examine the rectum with a large ivory-headed probang, and I found, at a certain depth (which was afterwards found to correspond with the point where the rectum was twisted), a slight obstruction to the passage of the probang; however it passed up with little difficulty, and was withdrawn without any. A piece of the intestine of an animal,

tied at the end, was carried up beyond this point, and then strongly distended by injecting water into it. In this distended state it was retained for some time, and then slowly withdrawn; but no discharge followed, though, as I have already mentioned, the distended part contained only air and fluid fæces.

The case is valuable, on account of the singularity of the course of the sigmoid flexure of the colon, and the minuteness with which it is described. It is to this case that allusion is made above in speaking of the possibility of a twist occurring in an angular portion of intestine, such as is the sigmoid flexure. Here the two contermious portions of the colon, forming the angle, were turned half round each other; but it is obvious that there is no physical impediment to their making a complete revolution, or even more than one: but what force acting within the body could produce such an effect? The cause of the obstruction seems not to have been the twist, but the compression of the lower end of the colon, between the proximal end of the sigmoid flexure, greatly distended, lying in front of it, and the inflated small bowels lying behind it. This is, therefore, the very same kind of obstruction that occurred in the case first narrated, only arising from a different disposition of parts. The marks of inflammation observed, render it probable that the patient's death was accelerated by that cause, and did not proceed from mere over distension of the belly, which was no larger than that of a woman at the full period of gestation. The author indeed, has ranked this case among those unconnected with mechanical obstruction of the bowels. He seems, also, to have looked upon the length of the sigmoid flexure of the colon as the effect of distension, and not of original conformation.

The only other case which I have to bring forward occurred in our own city, and was treated by the late Dr. Richard Miller, in the Royal Infirmary, in March 1819. No account of it, so far as I know, has yet been published. The following abstract is taken from the 14th volume of the Manuscript Essays of this Society:—

Michael O'Connor, æt. 47, labourer. Nothing had been passed through his bowels for seven days before his admis-

sion into the hospital, and he had been previously subject to constipation. His belly was much swollen and tympanitic. The strongest purgatives and injections were administered without any effect. Dashing cold water upon the feet, and every thing else that could be thought of, was tried, but the bowels could not be moved. Meanwhile, the swelling of the belly gradually increased, and before the patient died, the integuments and muscles of the abdomen were so much upon the stretch that "the convolutions of several of the intestines" could be seen through them. Death took place three days after admission to the hospital, and ten from the time of the last alvine discharge.

The stomach was healthy, and quite empty. The small intestines were greatly distended by flatus of an extremely fætid odour. The colon was also most enormously inflated, particularly the ascending and tranverse portions. The left colon, again, and the sigmoid flexure, were literally stuffed to the utmost with fæculent matter, and about six inches in diameter. At the termination of the colon in the rectum, over the promontory of the sacrum, the gut formed a turn on itself, from left to right, as if half twisted round. From the pressure exerted from above, by the "extreme" collection both of excrement and air, this twist was found to form a complete obstruction. The mucous tissue of the intestines, especially of the colon, was of a reddish colour throughout. This appearance did not extend beyond the twist, in the situation of which it was of a much deeper hue than elsewhere. The rectum was empty, and of its natural colour. The peritoneal covering of the bowels was every where natural, as well as the other abdominal viscera. It is to be regretted that nothing more is said of the length and course of the sigmoid flexure of the colon than that "this part of the gut lay more inclined towards the linea alba than in its natural situation;" and at another place, that "the sigmoid flexure was inclined, and actually a little displaced upward."

SUCCESSFUL CASE OF EXTIRPATION OF THE UTERUS.

To the Editor of the Medical Gazette.

SIR,

You will greatly oblige me by the insertion of the following case in your valuable periodical.—I am, sir,

Your obedient servant,

J. BOWER HARRISON, M.R.C.S.L. &c.

Lower Mosley-street, Manchester.
April 10th, 1840.

Marianne Morris*, æt. 28, was admitted a home patient of the Manchester Royal Infirmary, on the 5th of Dec. 1839. She was complaining of a discharge from the vagina, from which she had suffered for a considerable period. The constitution appeared evidently to have been much injured by the continuance of the disorder; the countenance was of a pale exsanguineous aspect, and the whole frame in a deranged and debilitated condition. The slightest exertion occasioned a considerable acceleration in the motion of the pulse, together with a somewhat difficult and hurried respiration. She stated that she was troubled with occasional pains in the loins and thighs, and had rheumatic pains in the shoulders and various parts of the body. The tincture of sesquichloride of iron was prescribed in the infusion of quassia, but it was not attended with any apparent relief. The acetate of lead was afterwards employed for a short time, but with a similar want of success. Upon a more particular investigation of the case, I learned that the discharge was frequently of a bloody nature; and she subsequently acknowledged the existence of a bearing down, for which she had been advised to employ a pessary, but was unable to continue its use. I then suggested the necessity of an examination, from which I discovered that the uterus was inverted. Upon her forcing down, whilst in the sitting posture, I was enabled to make a very complete examination of the tumor; it was of a pyriform shape, and presented, at the fundus, a smooth globular surface, which bled profusely on the slightest touch. At the neck it was surrounded by the reflection of the mucous membrane, which formed a little band, embracing the cervix uteri.

It seems that, about five years ago she was delivered of a female child, and, according to her representation, the placenta was hastily brought away, so that it is probable the uterus was inverted during its removal. It does not appear that she had been previously subject to a prolapsus of the womb, which has been considered, in some cases, to have been a predisposing cause of this affection*.

The uterus, having been so long inverted, had, no doubt, undergone considerable structural alteration, so that all attempts to reduce it were found unavailing. It was thought advisable, therefore, as the woman was rapidly falling into a hectic state from the repeated losses of blood which she sustained, and the continued irritation kept up by the mechanical action of the tumor, to propose an operation for its removal. To this the woman readily acceded; indeed, it will be easily imagined that her condition must have been of the most distressing nature. After going to stool, she had, at times, great difficulty in replacing the tumor, which could not always be accomplished without the aid of an assistant; and these occasions were almost invariably productive of considerable discharges of blood.

Accordingly, I passed a ligature round the uterus, on the 29th of Feb., 1840, at about half-past 3, p.m., assisted by Mr. Gaskell and Mr. Smith, the house-apothecary, and surgeon of the infirmary. The operation was performed whilst the uterus was forced down by the patient, who was in a sitting position. The instrument which I used was a simple rod of iron, pierced at the extremity with a small round aperture. The ligature, which consisted of three pieces of the ordinary kind, twisted together, was passed round the uterus a little below its neck, the two extremities being drawn through the aperture at the end of the instrument, and fastened to some small projections at the handle.

The ligature being properly tightened, the handle of the instrument was secured to the thigh by a bandage, which was also passed round the waist, in order more effectually to prevent any disturbance of the instrument. I saw her again at 8 p.m.; she had evacuated the bladder, and was tolerably easy.

The following particulars are tran-

* Residence, Sandiford's Court, Print Street, Buxton Street, London Road.

scribed from the memoranda which were made at the periods of their respective dates :—

March 1, half-past 9 A.M.—Complains of considerable pain in making water, of which she had parted with a considerable quantity; has slight pain at the umbilicus, but no pain in the neighbourhood of the uterus: she passed a tolerably quiet night, but has not had much sleep; she had taken a little gruel shortly before I saw her, but it was rejected immediately afterwards. 2 P.M. Has made water again, but still complains of the pain which it occasions; the bowels have not yet moved; the tongue is clean, and the pulse regular. Half-past 8 P.M. Is rather more restless; complains of tenderness in the abdomen, and pain in the back and loins; has taken a little tea and toast, which have staid on her stomach; warm flannels were directed to be placed on the abdomen; they did not, however, give much relief; the tumor is of a livid gangrenous appearance, and emits a fetid smell. The following draught was ordered to be taken at bed-time :—

R Træ. Opii, ℥xxiv.; Mist. Am. Acet. ʒj, M.

March 2, half-past 7 A.M.—Has passed a tolerably good night, though she has not had much sleep; the tongue is clear, and the pulse regular; she still complains of tenderness in the abdomen, together with a griping pain. As the bowels have not yet been opened, to use the common enema. The urine comes away in drops; but on passing the catheter I satisfied myself that there was no retention.—Half-past 7: The enema has operated on the bowels, and in part relieved the uneasy feelings which were experienced; she cannot now perceive any sensation when the tumor is touched, but is immediately aware if the handle of the instrument be moved: the smell from the tumor is exceedingly offensive, for which she was directed to bathe the parts with a solution of chloride of lime: to take the draught as before.

March 3rd.—Has passed a good night, and seems going on well; the pain in the abdomen is easier; the urine continues to dribble; the tumor appears to project considerably further from the pudendum, and has a more gangrenous appearance; the smell is less offensive. At 7 P.M., I saw her again, with Mr. Gaskell: she said she had not been so well during the last half hour, having

had more pain in the abdomen, but does not seem materially altered: the pulse continues natural, the skin cool, and the tongue clean and moist; she has no headache or thirst. It was thought advisable to tighten the ligature, which was done by drawing the string downwards, and holding it firmly against the handle of the instrument, while it was secured: she was afterwards ordered a draught containing 24 drops of the tincture of opium, which was to be repeated at bed-time.

March 4th.—Since the ligature has been tightened, she has had much pain in the loins and iliac regions; shooting towards the uterus. The water continues to dribble. The first draught was rejected, but the second remained on the stomach. She slept for about an hour during the night. A chamomile bag to be placed on the abdomen. As she has not had the bowels moved since the enema was administered, I ordered her a few grains of rhubarb and calomel, which were to be repeated if necessary; after the operation of which she is to take two tablespoonfuls of the following mixture three times in the day :—

R Morphine Acet. gr. ij.; Mist. Am. Acet. (Pharm. Manc.) ʒxij. M.

The tumor appears to protrude much farther than before, and is greatly augmented in bulk.

5th.—Has experienced some griping pains in the abdomen, which were, no doubt, attributable to the operation of the powder. There is no apparent alteration, if I except a greater protrusion of the tumor.

6th, 12 A.M.—Continues better; the tumor seems to project further from the pudendum, so that the part which is embraced by the ligature is now evident: there is a distinct groove at the line of demarcation, the membrane above being of a bright red colour. She experiences considerable pain in voiding the urine, which continues to dribble as before; the catheter was passed, but the bladder did not contain any quantity of urine.

The uterus, which is now very much increased in size, occasions an unpleasant dragging of the neighbouring parts, and, together with an offensive discharge from the surrounding membrane, has produced a troublesome excoriation of the nymphæ and perineum.

6th, 9 A.M.—Has a slight appearance of exhaustion, and the tongue is a trifle more dry than before. Mr. Smith accompanied me to-day, and we tightened the ligature, which gave her a good deal of pain. At Mr. Smith's suggestion, I ordered her a grain of sulphate of quinine and half a grain of opium, to be taken three times a-day.

9 P.M.—Has been more restless, and seems more fatigued; complains of much pain in the back and thighs.

R Tr. Opii, ℥xxx. h. s.

7th, 9 A.M.—Has passed a better night, but complains of tenderness over the pubes, and has vomited during the night*. To have an enema.

8 P.M.—Appears considerably worse. She has had much pain in the abdomen, also in the left groin, and in the course of the round ligament. She is very restless, and the countenance has an appearance of great depression.

To omit the Quinine, and take a grain of Calomel and Opium every four hours. Six leeches to be applied to the left groin.

The enema had operated on her bowels.

8th, 8 A.M.—Has passed a tolerably good night, but has an appearance of anxiety and exhaustion.

R Ammon. Sesquicarb. ʒss.; Aquæ Fontan. Mist. Camph. aa. ʒiij.; Tr. Opii, gtt. xxiv.; Cap. f ʒi. ter indie. To take a little porter, and have a more generous diet.

At night she seemed rather better; the food staid on her stomach, but as the medicine seemed to make her sick, she was directed to discontinue its use; the bowels were moved during the course of the day.

March 9th, 9 A.M.—Has not had much sleep during the night, but seems rather better. She has occasional lancinating pains in the groin, and some pain over the pubes. She takes a little wine and porter.

March 10th.—Has not passed a good night, and is rather fretful this morning;

* It may be excusable to state, as a curious instance of the rapidity with which the imagination works on the impressions of the senses, that during her sleep she dreamed that the various objects which she saw, on close inspection, were found to be in a decomposed or decayed state. She especially mentioned that she fancied some friend had kindly furnished her with some little articles of luxury; but, on coming to examine them, they were found to be in a state of putrefaction.

she does not, however, seem materially worse. The tumor appears considerably enlarged, and she complains much of the excoriation which it has produced. This I endeavoured to prevent as much as possible, by covering the tumor with pieces of lint, and afterwards folding it in a piece of oiled silk; also, by carefully sponging the adjacent parts.

R Træ. Opii, gtt. xx. h. s. s.

March 11th.—Has passed a better night, but is much inconvenienced by the excoriations. The separation is steadily progressing. The membrane above the ligature is covered with semi-transparent flakes of coagulable lymph.

March 12th.—Did not get her draught last night, and has not passed so good a night in consequence.

March 13th.—To-day I tightened the ligature, which occasioned a good deal of pain in the loins, pubes, and groin. To have an opiate.

March 14th.—No record kept.

March 15th.—I again drew the ligature tighter, which produced much pain as before, especially in the left groin.

March 16th.—No record.

March 17th.—The ligature was tightened.

March 18th.—To-day the uterus unexpectedly became detached as I was tightening the ligature. There was no bleeding afterwards.

The tumor is very considerably augmented, being about the size of the human heart. It is of a pear shape, the apex being much attenuated. It weighed $14\frac{1}{2}$ oz.; and, on making a section of it, the parietes were found to be more than an inch in thickness; in some places nearly two inches. On the outside it presents a dead, disorganized appearance; but the section displays a fleshy character, and by no means a decomposed texture. In some measure it resembles a section of the liver, the veins being exactly like those seen on cutting that viscus. At the extremity, at which the uterus had separated, which was very small, a nerve was discovered, about the thickness of an ordinary sewing needle. It was probably to the situation of this nerve that the pain which was experienced in the pubes and groin was owing. At that part of the tumor with which the ligature had been in contact, a distinct margin was discoverable, presenting a cartilaginous character.

March 19th.—She has not passed a good night, and complains of pain in

the throat on swallowing, and of an aching sensation in the limbs.

R. Mist. Antimonial (Pharm. Manc.) ʒj.
Appl. Hirud. iij. gutturi.

On the 20th and 29th, she continued to suffer from an aching sensation in the limbs; she had also much pain in swallowing, and a feeling of soreness throughout the whole length of the alimentary canal. There was a slight eruption visible at the corners of the mouth. I directed her to take linseed tea.

After this date she rapidly recovered, and is now fairly re-established in health, and able to pursue her domestic occupations. There is already a manifest improvement in the appearance of the countenance, and every prospect of permanent advantage.

CURE OF SQUINTING.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of sending you a short paper on Strabismus convergens, as cured by me by division of the rectus internus muscle, and shall feel obliged by your giving it an early insertion in your valuable journal.—I am, sir,

Your obedient servant,

A. FRANZ, M.D.

10, Golden Square,
April 15, 1847.

In the beginning of February, in reading the *Berlin Medicinische Zeitung*, No. 46, November 12, 1839, I became acquainted with Professor Dieffenbach's important discovery for the cure of squinting by the division of the shortened muscle which draws the eye out of its proper position.

With the view of ascertaining whether after division of the muscle the healing process would favourably go through its stages, notwithstanding the motion of the eyeball, I determined to try the operation on a rabbit. In the presence of my friend, Mr. Steinhäuser, I divided the *musculus rectus superior* and *obliquus superior* in the right eye of the rabbit, and the *rectus superior* of the left eye, from which I also cut off about one line and a half. After the operation the animal was allowed for the space of one month to enjoy its full liberty, at the end of which term I had it killed. On

making a careful dissection of the muscles of the eyes, I found the *superior rectus* of the left eye not only to have attained its proper length, but also all the divided muscles of both eyes firmly attached to the sclerótica in their right position. Before operating on the living subject, in order to convince myself of the most simple and best mode of conducting this operation, I performed it several times upon dead bodies, and am now enabled to give an account of two cases which I operated upon on the 10th of this month.

CASE I.—Louisa McCleish, aged 18 years, a healthy girl, with large light eyes, affected with squinting, according to her mother's account, since her second year, and for which she could assign no cause, presented herself for operation, this defect being a great impediment to her in her daily occupation as sempstress. On examination, I found the left eye slightly inverted, but the right eye so much turned inwards, that one-third of the cornea was hidden by the inner canthus. She stated that the right eye was larger than the left, having been frequently told so by others; but this I found to be an error, probably arising from the circumstance that so little of the cornea was visible, whilst a large portion of sclerótica presented itself. With considerable exertion of will she was scarcely able to direct the right eye so as to look straight before her, and could not in the slightest degree move the globe towards the exterior angle. When not under the influence of the will this eye instantly returned to its usual position inwards. On closing the left eye she could only distinguish large objects, and was not able to read even the largest print.

Having provided myself with three assistants, the patient, whose left eye was closed by a bandage, was seated facing the light with her head inclined backwards, in which position it was retained by an assistant, who at the same time fixed the upper eyelid with a retractor. A second assistant kneeling before the patient, fixed the lower lid by means of a retractor, held in his right hand: the eyelids being by these means well secured and drawn asunder, I perforated the conjunctiva at the inner corner of the eye close to the eye-ball, with a small and very sharp hook, and gave it to the second assistant to hold with his left hand, with which he was by

means of this hook to draw the globe outwards. I next made a semicircular incision with a scalpel through the conjunctiva, about six lines in length; then dissecting through the subjacent cellular tissue, exposed the internal rectus muscle, and terminated the operation by dividing it close to the sclerotica with a very small pair of curved scissors, the one blade of which was passed beneath the muscle. The duty of my third assistant was to hold the patient's hands, reach me the instruments, and attend to the bleeding, which in this case was very inconsiderable. On the removal of the hook from the conjunctiva, the eyeball was no longer inverted, but stood in the proper position, the pupil occupying the centre of the eye. The edges of the wound in the conjunctiva were brought together by the motions of the eye itself, which were perfectly free in all directions, except inwards. Cold water dressings were ordered, and a common draught. The patient then walked home.

I saw her again in the evening, when no febrile symptoms had made their appearance: the conjunctiva was slightly reddened; no pain was present; the motions of the eyelids and globe were free, the pupil was in its proper position, and since then the patient has been doing well.

CASE 2.—Emma Mattocks, aged 17 years, a girl of strumous habit, with a dark eye of moderate size, having squinted, according to her mother's report, since her fourth year, but for which she could assign no satisfactory cause, submitted to the operation in order to be freed from the deformity. The right eye slightly diverted, but the left in this case was turned inwards to such an extent that in the usual position the inner margin of the cornea was in contact with the caruncula lacrymalis. She could, with some effort, turn this globe a little beyond the centre of the eye, towards the outer angle; but with cessation of this effort of the will, the eye instantly returned into its former inverted position. On closing the right eye, she could not read even large print. The operation was, in this case, performed as in the former instance, and there was here also hardly any hæmorrhage. On removing the hook from the conjunctiva, the eye turned somewhat outwards. The motions of the eye were likewise perfectly free, and sufficed to bring the edges of

the wound in the conjunctiva in contact with each other. The same directions were given for the after treatment as in the former case, and the patient then walked home.

On paying my visit to her in the evening, no febrile symptoms were present; the conjunctiva slightly reddened, a trifling degree of pain, the motions of the eye-lids and globe free, the pupil still turned a little outwards, but not so much as immediately after the operation. On the next day, the conjunctiva was a little more injected, and the pains had not subsided, which I attributed to a cough, from which she was suffering at the time, causing a great determination of blood to the head. The pupil now stood in its proper position, and the motions of the eye were free. Six leeches were applied to the left temple, a hot pediluvium, a strict antiphlogistic regimen, and cough mixture ordered. Since then, the case has been proceeding favourably*.

In a letter of March the 28th, which I received from Dr. Dieffenbach, he states, that he had, on that day, operated on the 41st case—in all with an equally favourable result, so that in a fortnight after the operation it is impossible to distinguish which eye had been affected.

MEDICAL GAZETTE.

Friday, April 17, 1840.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MORTALITY OF THE FRENCH AND ENGLISH ARMIES.

ALTHOUGH the French have served a pretty long apprenticeship to constitutional liberty, there is one of its advantages which they have scarcely yet learned to appreciate: we mean publicity, or the diffusion, throughout the people, of that official information which, under a despotism, is confined to the favoured few. Thus a late writer in the *Gazette Médicale*, after mentioning

* The further progress and result of these cases will be reported in a future No. of this journal.

that General Paixhans had endeavoured, in the Chamber of Deputies, to obtain official documents relating to the health of the French troops, thinks that the refusal of the government to furnish them was quite justifiable. Indeed, he is of opinion that such painful facts had better be kept quiet; "*ce n'est donc pas nous qui aurions fouillés dans les données de l'arithmétique funéraire et déclaré aux jeunes générations les chances de destruction qui les attendent sous les drapeaux.*"

The commentator*, however, thinks that, as the figures have been openly published by the General, it is lawful to discuss them; and he believes that every cause which contributes to augment the mortality of soldiers is capable of being obviated. Surely, then, General Paixhans deserves no blame for having "rummaged the data of funeral arithmetic;" and if censure must rest somewhere, it should be on the heads of the ministry, who, by refusing to set forth the extent of the evil, have refused the first step towards correcting it.

It appears, from this demi-official account, that the annual mortality of the French army is 75 in 1000, in the colonies; 70 in 1000, in Africa; 20 in 1000, in France; and 22 in 1000 in the whole army.

This is a greater mortality than occurs in the English service. Thus we find, in Mr. Marshall's excellent work †, that, in fourteen foreign stations out of fifteen, the annual deaths per thousand are less than 70. At Gibraltar, for instance, they are 22.3; at Malta, 22.3; at Bermuda, 28.9; at Bombay, 33.1; in Bengal, 44.5; and at Madras, 52.2. But, then, on the other hand, in the Windward and Leeward Islands, they are 67.0; and at Jamaica, 91.0; so, at the

stations whose climate most nearly resembles that of the French West India Colonies, there is but little, if any, superiority to boast of. But, while the annual mortality among the troops stationed in France is 20 per thousand, the deaths among our troops, at home, are only 15 in the same number.—(Marshall, p. 59.)

Here the difference is clearly on our side; a difference which may be attributed in part, we suppose, to British soldiers being better fed and lodged; but in part, also, to the more fastidious selection of men for the army. In France, where the conscription reigns, the question always is, whether the infirmities of a given man are sufficiently urgent to exempt him from service; in England, we rather ask whether some slight ailment, which the recruit would fain conceal, will allow of his admission into the army. Moreover, it has always been made out that the general mortality in this country is less than in France; and it is natural that this greater tenacity of life should extend to the soldier as well as the civilian.

The commentator in the *Gazette Médicale*, first points out the advantages of the soldier over the ordinary civilian, and wonders that the average mortality in the army is 22 per 1000, while in civil life it is only from 12 to 14. There is an error here, in both his statements. First, in comparing the military and civil mortality, we must leave out of the question the deaths caused by the burning sun of Martinique, Algiers, &c.; a deduction which will make the annual deaths 20 instead of 22. Secondly (which is a more important mistake), M. L. has understated the deaths of civilians in France by one-half. In a paper read before the *Académie Royale des Sciences* at Paris, by M. Moreau-de-Jonnés, in 1833, he stated that the annual mortality in France was 1 in 39. This will

* He speaks of himself as one of the medical staff at the Val-de-Grâce, and signs with the initials M. L. Can this be *Méridée Lucmce*?

† On the Enlisting, Discharging, and Pensioning of Soldiers, &c., second edit. p. 58.

make $25\frac{1}{2}$ in 1000, instead of 12 or 14; and will most materially affect M. L.'s statement. But even when corrected, it is startling enough. How is it, one might ask, that the army in France should lose 20 in 1000, though it consists of picked men, chiefly between the ages of eighteen and thirty, while the community loses but $25\frac{1}{2}$ in 1000, with its crowds of old men and infants, and the host of the sickly to whom life has been but a long disease?

To make the paradox more striking still, we may give some advantages of the soldier over the civilian, as enumerated by our French fellow-labourer.

Each soldier, he says, costs the state 500 francs (20*l.*) a year, being far more than falls to the lot of a great part of the civil population. Hence the soldier is better fed, clothed, and lodged, than half the workmen in manufactories: he does not vegetate in an atmosphere saturated with miasmata, or filled with noxious vapours or foreign particles; but military duty is performed in the open air. The uniform, too, is a moral stimulus, giving new life to the weak and timid. Each captain is the father of a family, and his lieutenants assist him in watching over his children: one looks to the soldier's arms, linen, and bedding; another to his diet, and the management of the expenses relating to it. The soldier is admitted into an infirmary on the very first symptoms of disease; unlike the workman, we may add, who too often toils on until all hope of recovery is gone.

How comes it to pass, then, that with picked men, and with so many aids to life, the mortality among soldiers should approach so nearly to the mortality of the mass of the people? In the first place, according to M. L., the French army does not consist of such *very* select men, although not only the *gens du monde* but even the majority *de nos confrères* imagine that it does.

They think of a soldier as of a combination of agility and muscular force; while, in the military hospitals, and in the ranks too, you will find a multitude of young men, thin, pale, and blanched, with a narrow chest, and short breath; some exhausted before their time by laborious occupations, or the irregular life of great towns; others surprised by the conscription before their frame was completely developed, nature having been behind the law, and not furnishing the quantum of military strength at the legal age.

The second reason assigned by the writer in the *Gazette Médicale* is the frequent transference of troops from one part of France to another. The men are fatigued by the march; some fall ill by the way, and more are sent to hospital on their arrival. Moreover, the climate varies extremely in different parts of France; and, even in the same kind of climate, it is necessary to take into account a variety of circumstances: as, for instance, to determine what regiment will best be able to support a marshy encampment.

We certainly do not agree with the practitioner of the Val-de-Grâce, that the frequent change of quarters is pernicious; on the contrary, in spite of some of the weaklings dropping by the way, we are sure that variety of atmosphere and scenery is as enlivening for soldiers as civilians. On the other hand, when a regiment serves an unusual length of time in one place, and that spot an unpopular one, it produces absolute despair. The 9th regiment served from 1719 to 1746 at Minorca, and maiming became so prevalent among the troops stationed in the island, as to lead to a parliamentary investigation, (Marshall, p. 146-7). If, however, it so constantly happens that men are unable to continue their march, or are entirely knocked up at the end of it, the remedy is simple enough.

The third cause assigned is nostalgia. We doubt the frequency of this affection, at least among British troops; though it might sometimes be put forwards by the soldier as the pretext to conceal the deep discontent which devoured him; and even in his own heart he might mistake his dissatisfaction with the barrack for a desire to revisit his home.

Fourthly, says M. L., the diet of the French soldier is not quite sufficient, for his pay of 30 or 32 centimes (threepence) will not buy enough food. We should say that the English soldier's rations were very insufficient if they were limited to the quantity which the utilitarians assert. But if, as we quoted from Dr. Hennen on a former occasion, the soldier has one pound of meat and two pounds of bread a day, there is not much cause of complaint, though a supply of vegetables would be a desirable addition. At any rate, the 48 oz. given to the British man-at-arms, are far more than can be bought in France for 32 centimes. In moist and marshy situations, says M. L., wine should be distributed: it might be distributed here also, if our trade with France could be put on a more sensible footing.

The fifth reason is the badness of the barracks. In most French towns, the buildings in which the troops lodge were not originally intended for them; and when churches and convents are turned into barracks, it cannot be expected that they should be very healthy or commodious. As metamorphoses of this kind have seldom taken place in England, we may hope our barracks are more wholesome; but we fear that they are neither sufficiently spacious, nor well ventilated.

The sixth cause of the excess of mortality in the French army is the management of the hospitals. First of all, the surgeons have the right of treating a certain number of cases in the regimental infirmaries, instead of sending them to the

general hospital; and this, it seems, is disadvantageous to the patients, who in their *chambrées*, or roomfuls, sometimes escape notice. In the hospitals again, as in the barracks, the beds are crowded, and infectious diseases are placed indiscriminately among the others.—Convalescent establishments, too, are wanting.

Such, says our philanthropic colleague, are some of the causes which concur to produce the mortality of the army; there are many others, the examination of which would perhaps lead him to delicate questions.

Now, it strikes us that the real solution of the problem lies among the delicate questions; and that those which are discussed by the physician of the Val-de-Grâce, do not clear up a tenth part of the difficulty. Crowded hospitals and scanty rations are evils which diminish the probability of life; they are evils which might and ought to be corrected; but, after all, the soldier's diet is better than the labourer's, by the original supposition; nay, add all the other causes expounded in our contemporary, and the sum total will yet be insufficient.

The true explanation is, that man is not a machine, but that military discipline tries to make him one. For the soldier, the delights of domestic life scarcely exist; and he finds, to his cost, that four walls and a roof do not make a home. When to this moral depression, we add the forced servitude of years, perhaps without a limit, we shall understand the despair which makes the soldier mutilate himself; we shall almost comprehend why "the ratio of cases of self-murder among the cavalry branch of the service has been found to amount for a series of years to one suicide out of twenty deaths."—(Marshall, p. 141.)

Let us, therefore, improve the soldier's condition; let us enlarge his barracks and increase his rations; let us mitigate

the torture still inflicted under the name of flogging; and let us enlist recruits only for a term of years.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

April 7, 1840.

SIR B. C. BRODIE, Bart. in the Chair.

Identity of puerperal peritonitis with epidemic erysipelas.

A PAPER was read, transmitted by Sir James Clark, written by R. Hutchinson, M.D., M.R.C.S., Physician to the General Hospital, Nottingham, of which the object was to state some circumstances tending to prove the frequent identity of puerperal peritonitis with epidemic erysipelas, and which occurred during a recent epidemic at Nottingham.

After excluding phlebitis and metritis, which the author considers to be by some authors comprised under the name of puerperal fever, and of which the imperfect discrimination he thinks may have introduced much of the obscurity and contradiction in the accounts and opinions of medical writers on puerperal fever, the conditions of the weather preceding the epidemic are stated, and the fact of coincident prevalence of erysipelas and puerperal fever in the same neighbourhood, and at the same time, is stated. A case is then related at length, which the author judged to be a case of puerperal peritonitis. It terminated fatally, but no anatomical inspection of the body was made.

Another case follows, also fatal, in which the peritoneal inflammation, with the effusions usually described in puerperal peritonitis, were ascertained on dissection.

A third case shews the occurrence in the same individual of peritoneal inflammation after delivery, and of erysipelas beginning in the left labium pudendi, and extending over large surfaces of the body with vesications and sloughing of cellular substance. The treatment is detailed, under which the patient ultimately recovered.

These cases all occurred consecutively, without intervention of any other attendance on a case of labour, in the practice of the same accoucheur, and were followed by other distinct cases of puerperal peritonitis, one of which, attended by the author of the paper, in company with the same practitioner, exhibited repeated alternations of peritonitis and erysipelas on the surface.

The author then states that two practitioners, residing ten miles apart, met half way from the residence of each in attend-

ance upon a patient suffering under extensive erysipelas of the legs, with sloughing which required incisions to be made, in which both were engaged in handling the parts affected. One of them, the same evening, attended a patient, previously healthy, who died of puerperal peritonitis. The other, during the two following days, attended three cases of midwifery, in all of which death followed from puerperal peritonitis. The author draws from these observations a serious caution to practitioners of the danger of communicating infection. He mentions, among other writers who entertained views similar to his own respecting the identity of puerperal peritonitis and erysipelas, Mr. Ingleby, of Birmingham, who, in the *Edin. Medical and Surgical Journal*, 1838, speaks confidently of his conviction on the subject.

ASSOCIATION OF PHYSICIANS, DUBLIN.

At a meeting of the Association, April 6th, Dr. Robert Collins, president, in the chair, the Secretary, Dr. Thomas Brady, said he supposed the members had all seen a report in the newspapers, of a trial of a private in the 38th regiment, Andrew Hume, at the last assizes of Kenagh, for the murder of a female infant, only 11 months old, in an attempt to violate its person.—The prisoner was convicted and sentenced to death. In the published account, the chief part of the medical evidence was suppressed, but the case being of great interest in a medico legal point of view, he had written to the medical witness, surgeon Kingsley, of Templemore, and through his courtesy was enabled to lay before the association the most important facts connected with it.

On the march of the regiment from Rosena to Templemore, Hume, who was with the sick car, took the child from its mother, Mary Hall, to carry it some way for her. Hall is the wife of a soldier in the same regiment, and had not known Hume before that day. The child was quite well when he got it; he walked on quickly, and was out of her sight for half an hour. When she came up with him, he had the child standing on the grass facing him, and he was bent over it: with one hand he held the child's petticoats up, and his other hand was covered with blood. He said, Mrs. Hall, your child is very bad, it is passing blood. She took it up, rolled it in her shawl, and in this way carried it till they reached Templemore, when she went to an apothecary, where, however, no examination was made, and it was not till the

next morning that in washing the child the marks of violence were seen. This is the substance of the mother's evidence, which was uncontradicted.

When Mr. Kingsley saw the child for the first time, twenty hours from the time the outrage was committed, it was in a state of complete collapse, and in fact, died in a few hours afterwards.

On examination he found all the external parts of generation in a torn state, and violently inflamed; the perineum was torn nearly quite through; the nymphæ, and the mucous lining of the labia and clitoris, were likewise lacerated, so that the whole presented the appearance of a large lacerated wound in a high state of inflammation.

After death, besides the above, the vagina was found greatly dilated and torn from its attachment to the neck of the uterus posteriorly, making a large opening into the cavity of the abdomen, in which a quantity of bloody serum was effused.

The secretary then read a long and interesting paper from Sir Francis Smith, M.D., of Paris, a corresponding member of the association; but as it was sent for publication in the Dublin Medical Journal, we will not give at present any more detailed account of it here.

After which Dr. Churchill read a paper on the effects of parturition on the nervous system of the mother.

[The paper alluded to we shall give next week.]

GLANDERS.

To the Editor of the Medical Gazette.

SIR,

Your correspondent, Mr. Brush (at the conclusion of his case of glanders, reported in the GAZETTE of this day), seems to express a doubt whether that complaint can be communicated from one human subject to another. If he refers to the Lancet for 1831-32, vol. i. p. 698, he will find a case, occurring in Ireland, in which a father caught it whilst nursing his son, and both died. If he refers, also, to Travers on Constitutional Irritation, pp. 398 and 408, he will see that the glanders has more than once been communicated to animals by inoculation from the human subject. I hope that he will send to your journal the case of the nurse whom he suspects to have been inoculated, as soon as the symptoms become decided.—I am, sir,

Your obedient servant,

R. D.

Bruton-Street, April 11, 1840.

JACKSONIAN PRIZE.

THE Jacksonian prize for the present year has been awarded to Mr. Rutherford Alcock for his essay on Injuries of the Brain. Our readers may remember the appearance of Mr. Alcock's papers in this journal, in which they were originally published. His views are directly opposite to the doctrines hitherto taught, and are calculated to change both the diagnosis and treatment of such cases. We presume, from his obtaining the prize, that the Council regard his opinions as founded on accurate observation and reasoning.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, April 2.

J. B. Ayre.—G. H. Whimper, Tillingham.—S. J. Burch, Stowmarket.—A. G. Roper.—T. Gray, Louth, Lincolnshire.—T. W. Mann, Holloway.—R. D. Larke, Brooke, Norfolk.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF VEINS.

*General Remarks—Symptoms—Treatment.—
INFLAMMATION OR PHLEBITIS—Charac-
ters—Local Signs—General Symptoms—
Treatment.—AIR IN VEINS.*

THE structure of veins differs from arteries in more than one respect: their parietes are thinner and more flaccid; they are deprived of the fibrous tissue which gives to the arteries their elasticity, their form, and their aspect. They are composed of only two distinct tunics; the one, external, fibro-cellular, firmer, more resistant, yet very extensible, composed of longitudinal fibres, to which the veins owe their solidity; the other, internal, very thin, very smooth, polished, fragile, but more cellular than that of the arteries, forms, by its duplicatures, the valves which belong exclusively to this order of blood-vessels. It is sufficient to recollect the precautions which we are obliged to take in blood-letting, to feel that venous hæmorrhages may be spontaneously arrested; and the consequences of this operation prove that veins are not obliterated in this process.

The experiments of Travers on this subject are interesting and important. When we prick a vein through which blood circulates, a very little blood escapes, and the wound is soon cicatrized. If an incision of trifling extent be made, the result is similar, except, in some cases, when there is a slight interval between the lips of the wound, and a small quantity of

blood escapes; this may flow to the surface when the vein is superficial, or may infiltrate the adjoining tissues, if it be deep seated: in this case the cicatrix is more apparent than in the former, though still linear. But, if the wound be large, the fluid escapes, at first, abundantly; after a certain time a clot is formed in the opening, which it obliterates, whilst a certain quantity of extravasated blood passes into the cellular sheath, and coagulates, so as to constitute an external clot surrounding the vessel. At the end of twenty-four hours the lips of the wound, which has taken an oval form, are everted, and adhere to the clot without being red, and apparently without secreting coagulable lymph. In a short time a membranous expansion unites the clot to the vessel, the clot becomes soon organized, so that in twelve days, with the aid of a lens, blood-vessels can be discovered ramifying in it. If we make a transverse section of a vein, the blood escapes in a considerable quantity, and, if more than half the circumference be implicated, it is not easy to arrest the hæmorrhage; the blood escapes rapidly into the cellular sheath of the vessel, and into the surrounding tissues, and forms a clot which is interposed between the opening of the vein and the external wound; but the circumstances of cicatrization are the same as in arteries. In all cases the extent of clot which blocks up the opening is proportioned to the gaping of the wound. These remarks apply to the cicatrization of wounds such as result from venesection either in man or the horse. Thus, according to Travers, that which characterizes the cicatrization in wounds of veins, and distinguishes it from the mode of cicatrization in wounds of arteries, is, that wounds of veins, when the edges are in contact, heal by first intention; at first, by means of a clot which forms between the lips of the wound, without projecting into the cavity of the vessel, and afterwards by

means of a membrane which becomes organized. During this period the only trace of inflammation is the tumefaction of the lips of the wound within the vessel. My own opinion differs from that of Travers: I readily admit that venous parietes exhibit no very marked disposition to secrete lymph; still I have no question that lymph is secreted, and is the ultimate bond of union; that the membrane, described by Travers as at first connecting the clot with the lips of the wound, and afterwards stretching across, is the result of the transformation of lymph.

Travers has made experiments on the ligature of veins, from which it resulted that the internal tunic is not divided by the action of the ligature, but that it left a circular mark which some persons had mistaken for a solution of continuity. The external alone appeared to be cut. The part of the vessel nearest to the heart becomes completely empty, the opposite part is distended, the fluid coagulates for a considerable distance, and the coagulum becomes adherent to the venous parietes. Externally, around the ligature, lymph is deposited, and the surrounding tissue is infiltrated with the same fluid. Towards the ninth day the venous tunics begin to change, and, from the fifteenth to the twenty-fifth day, the ligature is detached, the extremities of the vessel are retracted, and an interval exists between them. In a young horse the ligature was not detached before the twenty-fifth day; and Travers ascertained that the extremities of the vein had not suffered any other contraction than that which resulted from the action of the ligature. The internal tunic was examined, the clots were carefully removed, and no thickening of the parietes or any vestige of inflammation was discovered in any part of the vein. According to Liston, no adhesion takes place until the ligature has produced ulceration, and then the canal may become obliterated.

Veins, being more superficial and less protected than arteries, are more frequently wounded; but the hæmorrhage consequent upon such wounds has not occupied much attention, though occasionally the consequences are most serious; especially when a large vein is about to penetrate into a splanchnic cavity; it may even be more dangerous than the wound of the principal artery of a limb, because, if the blood continue to flow, the patient may die from loss of blood; and if, to suspend it, the section of the vessel be completed, the patient may die from mortification, in consequence of blocking up the only way by which it could return.

Venous hæmorrhage is recognized by the following characters:—the blood is dark; it wells out, or by a feeble jet; the

quantity increases if the muscles of the limb be contracted; if we compress the vein between its radicles and the wound, the hæmorrhage is arrested; it is increased if pressure be made between the wound and the heart. When it is a question of a principal vein of a limb, or of one of the cavities, death may be the consequence of the loss of blood. Certain diseases of veins cause the accumulation of so large a quantity of blood, that when they are opened very abundant and dangerous hæmorrhage is the consequence. Many cases are on record of fatal hæmorrhage following the bursting of varicose veins. Although these may not strictly be called cases of traumatic venous hæmorrhage, yet a wound inflicted upon such a vein might, I apprehend, produce similar results.

Treatment.—The means proposed for arresting venous hæmorrhage are less varied than those employed in wounds of arteries. The most important condition to fulfil is to ascertain the cause. The depending position of the part increases the lateral efforts of the column of blood, and is a cause of the continuance of a hæmorrhage. It is, therefore, of the highest importance to ascertain whether respiration, position, or other circumstance, tends to keep it up. It is always wise to attempt to preserve the canal of the vessel, and this is often done when compression alone is sufficient to restrain the hæmorrhage. The application of the compresses in the common operation of bleeding at the bend of the arm is a proof of that. If compression be not applicable or effectual, and the wound is very narrow, an attempt may be made to get hold of the vein with a tenaculum, passing it through the lips of the wound, placing a ligature around that point, and thus preserving, as far as practicable, the continuity of the canal. At the same time the cure must be assisted by the position of the part, which, by facilitating the passage of the blood, diminishes its lateral pressure, and lessens the tendency to escape. When a vein is completely cut through, it cannot continue to be a channel of communication; it is, therefore, proper to attempt to obliterate it. Sufficiently energetic compression may be applied to the part; and if that do not suffice, each end may be included in a ligature. It not unfrequently happens, after amputation of the lower limb, that a vein continues to pour out blood upon the surface of the lymph: in this case the ligature is necessary, which, if the patient be in moderately good health, may be a less dangerous means than was supposed by Travers; still it is not an operation which should be heedlessly performed, because the occurrence of phlebitis after it has unhappily been but too frequent.

PHLEBITIS.

Injuries of veins may be followed by inflammation of those canals, which is an extremely grave disease, the symptoms of which Aretæus briefly pointed out. This subject has occupied a very large portion of the attention of medical men since the time of John Hunter. In examining the bodies of two horses which had died suddenly, after bleeding, he found the internal surface of the veins inflamed. Having occasion to open many abscesses, occurring in a man who had been bled at the bend of the arm, he found that they were developed in the course of the venous trunks, but that pus was also contained within the veins. In another case, a person, having died on the eighth day after bleeding, he found the internal surface of the vein covered with lymph. It is also developed after parturition, excision, and ligature of varices, amputation, lithotomy, &c. To be well acquainted with the ordinary characters of phlebitis, it should be observed after bleeding. Some hours after the operation, a prickling sensation is felt at the puncture, soon it amounts to pain, the little wound gapes, its lips are slightly tumefied, and sanies or sanious pus escapes from it. If all should go on well, this gradually subsides, and, by the seventh or eighth day, all is dissipated. If, on the contrary, the disease proceed, pain is manifested along the vein, it soon becomes tense, and swelling extends to the whole limb. If the vein be superficial or projecting, the skin is reddened along its course, the pain and tension increase, the course of adjacent veins is marked by a redness of the skin over them, the tumefaction increases, becomes œdematous, the inflammatory action extends towards the heart, the vein appears like a hard knotted cord; motion of the limb is then painful and difficult, the cord becomes thicker, abscesses are sometimes formed around it, and erysipelatous redness is occasionally intense. But too often it happens that pus finds its way to the viscera, and the symptoms become very urgent. Severe rigors, sometimes continuing for hours, are felt, the skin becomes pale or yellow, and there is rarely much re-action. After two or three paroxysms, typhoid symptoms are commonly developed. The eyes look hollow, the conjunctiva yellow; the tongue, which continues moist, is not deeply coated until the later stages of the disease; the teeth and lips become fuliginous, the pulse, at first hard and frequent, becomes small and feeble, tympanitis, or diarrhœa, rarely delirium, supervenes, though there is a good deal of stupor. In some cases there are vague indications of visceral inflammation. Sometimes there is a livid spot

on each cheek, short frequent cough, pain in the chest, and difficult respiration; sometimes icterus, with pain over the liver, or in the right shoulder; sometimes vomiting and gastric irritation; and the breath is very fetid, yielding a purulent odour. Cicatrization of the wound is suspended; suppuration becomes greyish, or even entirely suppressed, and the subject dies exhausted in two, three, four, or five weeks. The post-mortem inspection reveals two species of lesion; those belonging to the vein or veins themselves, and those which are a consequence of phlebitis. We see the vein transformed into a reddish cord; the cellular tissue connected with it is infiltrated with a sero-purulent fluid: the redness and vascularity of the external tunic is very decided, and very characteristic. The interior of the vessel may contain blood or pus, the inflammation may produce obliteration by means of the clot, the pus may be limited by a clot, the vein may be perforated, or the pus may circulate with the blood. In the latter case, a large number of visceral abscesses are produced.

The consequences of phlebitis had been greatly discussed at a much earlier period, but the disease which gave rise to those alarming symptoms, the consequence of "purulent absorption," was comparatively unknown; and even when ideas on the subject were becoming more defined, a great struggle took place between the partisans of phlebitis and those of purulent absorption. The difference between the doctrines was not great: both started from the same point, a wound or operation—both admit a change in the blood—both maintain that this alteration proceeds from the admixture of pus with the blood; their difference consists simply as to the manner in which the pus gets access to the blood. The doctrine of phlebitis implies a direct passage—an immediate admixture. The doctrine of purulent absorption maintains that the passage is indirect, and the admixture consecutive.

In the Transactions of a Society for the Improvement, &c. (1793) are the ingenious experiments of Hunter on the subject of phlebitis. He considered not only the local effects of inflammation upon the internal tunic of veins, but also the general effects.

Phlebitis belongs at the same time to medicine and surgery; there may be a traumatic phlebitis, and a spontaneous phlebitis. The first effect of all phlebitis is to produce coagulation of the blood, and adhesion of the clot to the parietes of the vessel. This is observed whether the affection be traumatic or spontaneous. From the interruption of the circulation in an inflamed vein results the stagnation of the venous blood, and the effusion into the ad-

joining tissues of a certain quantity of serosity. Phlegmasia dolens after parturition, as well as after phlebotomy, may be considered as a characteristic sign of phlebitis; and this œdema is usually proportioned to the derangement of the venous circulation of which it is a consequence. Besides the œdema, phlebitis is characterised by the presence of a hard, painful cord, easily circumscribed, and following exactly the course of the vein. The greater number of cases of phlebitis, even when left to themselves, do not pass that limit which has for result the coagulation of the blood, and its adhesion to the parietes of the vessel. This may be termed *adhesive phlebitis*, and this happens as often as veins are cut through.

Adhesive phlebitis is a simple unimportant disease, and its effects are limited to the affected point. Gradually the serum contained in the clot is absorbed; then the colouring matter; and only the uncoloured fibrine remains. Sometimes this becomes organised; sometimes it is entirely removed; but in both cases the vein is obliterated. Now and then it happens that a canal is formed in the centre of the clot, and the blood circulates through it. The formation of compact adherent clots occasions no inconvenience, and does not even manifest its existence, unless it occupy a certain extent, and interrupt, to a greater or less extent, the circulation of corresponding parts. Thus, phlebitis of the sinuses of the dura mater is necessarily mortal in this first period, because the venous circulation of the brain is more or less completely intercepted. Phlebitis of the femoral vein, or the external iliac, produces œdema of the limb, and may occasion gangrene.

Suppurative phlebitis is, in its first stage, similar to *adhesive*. An adherent clot is the first stage, suppuration is the second. There are conditions, which cannot be clearly defined, under which a tendency to suppurative phlebitis is determined, whatever care may have been bestowed on the case; there are others, in which it seems to be the consequence of improper treatment. Certain miasmatic or individual peculiarities seem to determine it; among these are the causes which favour hospital gangrene, or typhus. Some persons, however, believe the typhus, in these cases, to be a consequence of the presence of pus in the veins.

Though very intense, if properly treated, adhesive does not often end in suppurative phlebitis. A great cause of this termination is an improper interference with wounds—with parts already inflamed. Attempts, for instance, made day after day to remove a sequestrum or a spicula of bone; or the plugging up of a wound to arrest secondary hæmorrhage.

Local signs.—The local signs of suppuration in veins are, first, when slight, red patches apparent on the inner surface of the vein; when more intense, instead of being thus marbled, it is uniformly red; it is thickened so that, when a section is made, the vessel remains open. The internal surface is sometimes smooth, sometimes unequal or ulcerated. In the arm, two days after bleeding, I have known the veins to look fleshy, and much thickened, their interior filled with pus, which is deposited not between the vein and the clot, but at the centre of the clot; and, by some persons, it is believed to be a change which the clot itself undergoes—first it is grumous, then sanious, then whitish, opaque, phlegmonous. This presence of pus at the centre of the clot, Cruveilhier believes to be a phenomenon of capillarity; that, like a false membrane, the clot serves as a filter, through which the pus passes. Sometimes this apparent suppuration is no doubt a softening of the fibrine itself. Suppurative phlebitis may not pass beyond this stage, and its existence may not be manifested by any symptom. If it proceed farther the coagulum diminishes, and the pus augments. Soon the vein is filled—distended with the fluid; but it is rarely that pus occupies uninterruptedly a large extent of the vein—the inflammation, varying in intensity, at one point may be adhesive, at another suppurative. Other circumstances occur. If the disease continue to be local, the vein is distended, knotted; this distension may be so great as to give rise to the idea of abscess: the venous parietes may give way, the pus be effused into the surrounding tissues, constituting abscess, and opening externally, the vein being destroyed to some extent, and not easily discovered.

It is well to distinguish between inflammation affecting the internal tunics of a vein, and that of the external or cellular; often they coincide, sometimes they may occur isolatedly. Rarely does inflammation of the cellular tunic end in suppuration; still there are examples of it. When suppurative phlebitis is limited by adhesive phlebitis, only local phenomena are manifested; that portion of the vein in which the pus exists is cut off from the general circulation. Among other examples of this we may mention the following:—Soon after parturition, a woman had phlebitis of one of the superficial mammary veins. It was hard, cord-like, and painful, extending from the external to the internal margin of the gland, a little above the nipple. A fluctuating point was presented, it was opened, and the vein was completely emptied; the projection which it had formed being succeeded by a groove. In fact, whatever extent of a vein may be affected by suppuration, provided it be limited by adhesive in-

flammation, local accidents alone will be presented.

This pus may be absorbed, as in any ordinary collection, and carried off by ordinary means; it may distend and thin the vein so as to allow of its destruction, and so cause abscess, which may be mistaken for common abscess: but as soon as the barrier formed by the clot is broken down, and the pus is mixed with the circulating blood, typhoid symptoms are immediately manifested, preceded by intense rigors, and soon followed by death. Frequently we find in a morning the condition of a patient desperate, whom we had left pretty well the preceding evening.

If we examine the internal surface of a vein at different periods of phlebitis, we never find upon its surface the ordinary traces of inflammation, that is to say, injection of the capillaries; the red colour, which is seen, looks more like the effect of imbibition—probably a post-mortem result, and only seen in the first stage. As the colouring matter of the clot is absorbed, the red colour of the surface of the inner tunie diminishes, and is entirely absent when pus exists in contact with it. It is important to carry this in our mind, because it is upon the absence of these signs of inflammation that the principal argument of those persons is based, who maintain that the pus found in a vein has not been formed there, but in some other part of the system, from whence it has been brought by absorption: but we cannot forget that there are membranes which are not susceptible of injection, neither in the healthy nor morbid condition; such are the serous membranes, the cellular tissue, and the internal membranes of veins. In the absence of an adherent clot, and of pus in a vein, it is by the vascularity of the external tunie, the cohesion and fragility of the external cellular tissue where lymph has been deposited, that we discover traces of venous inflammation.

General symptoms.—The general symptoms of phlebitis, as we have seen, are those which are usually attributed to purulent absorption; namely, extremely marked typhoid symptoms, under which the patient sinks with more or less rapidity. Upon examination after death, we find circumscribed purulent collections in the lungs, liver, spleen, brain, muscles, synovial and serous cavities; and, what is most singular, often unaccompanied by any local appreciable sign in the affected organ. Now, what happens here? Is there a development of preexisting tubercles? Is there purulent absorption—pus being taken up, as pus, from the surface of a wound, and deposited in different organs? or, Does the presence of these collections presuppose the existence of suppurative phlebitis in some other

part of the economy, a consecutive phlebitis being developed at the point where the abscess is found?

The first inquirers who sought to discover the cause of death after great surgical operations, have pointed out the existence of internal abscesses in the principal viscera, particularly in the lungs and the liver. Modern inquirers having observed the frequency and the gravity of these lesions, did not hesitate to ascribe to these causes the frequency of death; and whilst the surgeons of the last century continued to observe the wound, and exclusively sought, in the different appearances of the wound, the explanation of all the circumstances which succeed in the course of treatment, the better educated men of the present day, studying the local as well as the general condition, see in the different qualities of the pus, its quantity, and the colour of the integuments, a pretty certain index of the state of the viscera.

It is very difficult to explain visceral abscesses as a consequence of surgical operations, though operations are often performed on persons whose general health is good, and in whom we cannot admit that visceral lesions, so grave as those we meet with, can have existed before the operation. Still as, on the one hand, observation shews that a great many organic lesions may exist in a latent state; and as, on the other hand, visceral abscesses, consequences of wounds, present by their multiplicity, their seat, and other circumstances, a great analogy with suppurating tubercles, many persons have maintained that these abscesses were no other than the result of the development of pre-existing tubercles. If this theory ought not to be adopted as a general rule, neither should it be repulsed in all cases. Our own opinion is, that it should not be admitted as a general rule: unquestionably, in most cases, around these abscesses phlegmonous inflammation may be detected, without tubercles or tubercular infiltration.

Visceral abscesses being generally consecutive to wounds, it was natural to admit between them a relation of cause and effect; the question to consider is, how a wound which suppurates, determines purulent collections in the lungs, the liver, and so on? The first idea which was adopted was a pure and simple transport of pus from the wound into the viscus, or metastasis. This doctrine was supported on the following grounds:—The diminution or suppression of external suppuration, which is the constant prelude to the formation of internal abscess, the absolute identity of the pus on the surface of the wound, and that in the abscess, the absence of general and local symptoms to indicate visceral inflam-

mation; the rapidity with which these abscesses are formed; the presence of pus in the veins, and in the right cavities of the heart, in the midst of coagula. If we admit this doctrine, we must go a step farther, and ask, how is the pus conveyed from the wound to the heart? Reasoning rather than facts has been used to answer that question. The veins, it is said, absorb and convey it; the lymphatics have, it is said, performed the same office; and some persons believe that both participate in it. Velpeau, Marechal, and Legallois, admit, that pus secreted in the substance or upon the surface of the body may be absorbed, circulate with the blood, and be deposited in the substance of this or that organ, without previous inflammation of that organ. The facts they invoke in support of their opinion are undeniable as facts; what we object to is their mode of interpreting them. They have seen pus in the veins, in the right cavities of the heart, in the midst of clots of blood, in the lymphatics; others have done so too, and even in the lungs, liver, brain, spleen, muscles, synovial cavities, without any traces of surrounding inflammation. But this pus, so observed, may it not be formed at the point where it is found? May not the pus in a viscus be a consequence of circumscribed inflammation of that viscus? The diminution of secretion on the surface of a wound, may it not be the effect rather than the cause of the internal lesion? Unquestionably that would be the most rational interpretation: such was the opinion of Quesnay, Morgagni, and Dance.

The reasons which appear to us to favour the opinion that the pus is formed at the place where it appears are, that the formation of visceral abscesses is almost always accompanied by general symptoms, of a more or less grave character, which cannot be explained by the state of the wound. The absence of local symptoms in the situation of a viscus does not testify to the absence of inflammation of that viscus. Unquestionably a certain number of abscesses do not present, at the circumference of the cyst, any trace of inflammation. As to the rapidity with which the pus is formed, there is nothing astonishing in that, the duration of the disease being usually five or six days at the least.

Visceral abscesses are frequently idiopathic—formed in the substance of a viscus by inflammatory action. They are large tubercles, consequences of pneumonia or lobular hepatitis: this was Morgagni's doctrine. We must proceed further, and endeavour to ascertain the mode of formation of pus in a viscus as a consequence of wounds. Every foreign body introduced into the venous system determines, when it cannot be carried off by the emunctories,

visceral abscess in all respects similar to those which succeed to wounds or surgical operations; and these abscesses are a consequence of capillary inflammation in the organ where they are found. If we inject an irritating fluid into the femoral vein, if the collateral vessels do not carry the fluid into the circulation, (in which case death rapidly follows), at the end of thirty-six hours the limb is tumefied; and at this time, if the animal be destroyed, numerous clots will be found in the muscular and cellular tissue of the limb, and the larger veins are distended with adherent coagula. If the animal survive this period, pus or softened fibrine replaces the clots within and without the vein. If we divide the muscles, small collections of pus are seen, (it may be expressed from the small veins with great facility), and the synovial surfaces present purulent synovia.

In such cases the disorder may be local. It is important to ascertain what becomes of the pus, in local phlebitis, when it gets into the circulation; but as it is difficult (if not impossible) to recognize pus when mixed with the blood, it is necessary to give to the demonstration all the exactness of a physical experiment; to find a liquid which can always be recognized, and to follow its smallest molecules: that liquid Cruveilhier found in mercury. In whatever part of the venous system, other than the abdominal, we introduce mercury, the globules will be found in the lungs: they will not be found inflamed, but "engorged." If the animal survive some days, a reddish induration will be seen to surround each globule; at a later period, pus or tubercular matter, or a mixture of both, will constitute their circumference. Cruveilhier has even placed a single globule in the medullary canal of the femur, and a month afterwards he has found that globule in the lung, divided into many smaller globules, each being the centre of a tubercular abscess. Similar phenomena have been observed in the liver, as a consequence of a similar injection into the abdominal venous system. From these experiments, it results that the lungs are for the general venous system, and the liver for the abdominal system, an outlet for foreign bodies, and a barrier which, in many cases, they cannot pass. Thus the veins do not fill only the part of conducting the blood which has circulated through the arteries back to the heart, but they seem also to be capable of absorbing foreign bodies.

Those experiments to which we have referred assist in the solution of another difficulty. How does the pus get from the general into the portal venous system? This pus cannot be arrested in the lung like mercury, but passes in larger or

smaller quantity through the whole venous system: and we are justified in stating that pus, circulating with the blood, creates its peculiar irritation in every organ; in some more than in others; more decidedly and frequently in the lung than the liver or spleen. The next question to consider is, why do not these numerous abscesses supervene in those great collections of pus in the chest, the peritoneum, and in very large abscesses?—and is traumatic phlebitis necessary for their production? That great difference does exist between the consecutive effects of old purulent collections and recent traumatic suppuration, was strongly maintained by Quesnay. Why should there be absorption of pus in one case, and not in the other? Whenever a liquid susceptible of being imbibed is in contact with a suppurating surface, whether this liquid be secreted by our tissues or a foreign body, this liquid is absorbed. Absorption of pus goes on incessantly; the often-observed occurrence of the sudden disappearance of large abscesses is evidence of this. We see purulent collections in the pleura and peritoneum removed by absorption, and yet the economy is not disturbed, and the peccant matter is carried off by the emunctories. I wish you to understand that there is an enormous difference between pus which is transported by absorption into the circulation, and that which is formed in the veins. Absorption, it is probable, does not introduce the mass of purulent fluid, but successively the different elements. It seems first to remove its more liquid portion, its more solid parts are removed at a later period: but when pus is mixed immediately with the blood, it alters its crasis, embarrasses it in its course, favours concretion, is arrested in the capillaries, and determines simultaneously a number of points of inflammation. I only know three ways by which pus can be introduced into the circulation; by direct injection into veins or arteries, by attraction exercised by an open vein, by phlebitis. Now the direct injection of pus into the veins has the most serious consequences, and, if not eliminated, produces accidents analogous to those which succeed to wounds or surgical operations. A powerful attraction is, it is said, exercised by veins upon fluids in contact with their open extremities. This is the idea of Marechal, who, basing his opinions upon the experiments of Barry, maintained that pus is drawn into the open veins by the aspiration caused by expansion of the chest and dilatation of the right auricle. Certain it is, if the opening be maintained, a species of absorption does take place. The attraction can only occur during the first few hours after the first infliction of the

wound; when once the clot is formed, the absorption can no longer happen through the divided vessel, but must be effected, if at all, by the natural channels of absorption. Now I do not believe, for the reasons I have already given, that pus, in its natural state, can find its way into the general circulation through these channels. In that case, phlebitis alone would seem to be the only source of those accidents which succeed to wounds of veins. It must therefore follow, that visceral abscesses succeeding to wounds or surgical operation are a consequence of phlebitis of some part of the system; that they always present the same character, whatever may be the starting point.

I by no means admit that pus, secreted in an inflamed vein, and carried through different organs, concurs directly in this species of purulent generation, as was supposed by Dance; but I believe that pus, once mixed with the blood, is no longer pus, but an irritating foreign body. The rapidity of the formation of visceral abscess, the ordinarily perfect integrity of adjoining tissues, are not, in my opinion, decided objections against inflammation, for 48 hours is sometimes sufficient for the secretion of pus in an inflamed vein; and, on the other hand, the limitation of the pus, and the multiplicity of points where it is found, are explained by the inflammation of the capillaries. But this mode of looking at the question is not without difficulties: it would seem to be necessary that numerous visceral abscesses must always be preceded by phlebitis at some point. Now it often happens that we do not find at the same time with visceral abscess any thing more than a suppurating surface. In vain have we examined all the veins (not only those immediately around the wound, but those of other parts of the body), without finding any trace of phlebitis. In support of this view of the subject, we may take wounds of the head, which are so often accompanied with abscess of the liver; but no trace of phlebitis. Dance was the first who gave any thing like a true explanation of these abscesses of the liver, as a consequence of wound of the head: his theory is, that the deep veins are inflamed. We may readily conceive that pus, formed in the diploic veins, should arrive at the liver as well as the lungs and the whole capillary system, for the liver is not exclusively affected in wounds of the head; and if many observers have simply mentioned those of the liver, it is because, in many instances, they have been contented to examine only those viscera whose lesions have seemed to them to explain the symptoms which were present.

I have already stated that I know no

operations which more infallibly tend to the formation of visceral abscess, than those which are performed upon bones, when we frequently return to the charge. The same may be said of interference, day by day, with a wound in the soft parts. I think it ought to be established as a surgical law, that a wound in a state of acute inflammation should not be meddled with, except the necessity be urgent. Phlebitis of the superior or inferior extremities may occur with or without œdema: there is no œdema when the venous circulation is not much constrained—that is, when it occupies only superficial veins, the deep veins being free. There is œdema when the venous circulation is materially interfered with. Phlebitis with œdema, is generally termed *phlegmasia dolens*; it occurs commonly after parturition, and usually affects the lower extremities. Though often preceded by the symptoms of uterine phlebitis, it may sometimes be manifested primarily in the limb itself; commonly supervenes towards the eighth day after parturition, sometimes not until three weeks or a month afterwards. It is indicated by the presence of a hard painful cord in the course of the femoral vessels. The œdema is generally proportioned to the extent of the phlebitis, which may occupy the femoral vein alone or may implicate many others. Still there are contradictory points with regard to this subject. Cases of obliteration of the larger venous trunks—the inferior cava, for instance—have been known to occur without infiltration of the lower limbs. The fact is, I believe, that not only the large veins must be obliterated, but also the smaller ones, to produce these effects, so much facility being offered by the collateral circulation. This kind of œdema is not peculiar to lying-in women; it is sometimes spontaneous, is not unfrequently a consequence of cancer of the uterus, causing inflammation of the iliac or femoral veins. Sometimes it is seen in the arms, as a consequence of cancer of the breast. No part of this subject, however, is more interesting than purulent effusion within the joints. Are the cartilages inflamed? Is this intra-articular suppuration the result of a simple deposit of purulent molecules, or is it the result of local inflammation? Should it be confounded with rheumatismal arthritis? Is the membrane which invests the cartilages vascular in the adult? Is it susceptible of inflammation? In the absence of materials for the accurate determination of this question, I may state my opinion to be, that pus, as pus, is not deposited in those articulations.

Treatment.—With respect to treatment, it is very difficult to say how we can oppose purulent infection; theory would

seem to indicate the employment of diffusible stimuli and bark, warm applications externally, purgatives, and emetics—such as large doses of tartar emetic in the early stages of the disease, repeated blisters, energetic diuretics, calomel, to produce a fluxion upon the intestinal mucous surface; but all these means have failed, and yet, when we experiment upon brute animals, by injecting putrid substances or pus into the veins, the animal has numerous and very foetid stools, and gets well. It is certainly a fundamental fact in pathology, that the greater number of diseases occasioned by miasmatic infection direct their action upon the intestinal canal. It is, then, evident that the treatment of phlebitis should be directed to limit the disease to its first period—that of coagulation of blood; for suppuration once declared, pus once carried into the circulation, and our attempts to cure the disease will almost always be powerless. Now we arrest every day external phlebitis in consequence of bleeding, by the application of a great number of leeches in the course of the vein; and even can arrest internal phlebitis, uterine as well as other, by large evacuations of blood, local and general: but pass that period, let general symptoms begin to manifest themselves, general and local bleeding will rarely have any favourable influence. They, no doubt, remove with the blood a portion of the material cause of disease, but this material cause is incessantly reproduced; and by removing the blood, you remove a certain portion of the power of resistance or reaction. We are bound to use the remedies we have indicated, although their efficacy has not been demonstrated. Until we can invent some means of preventing the constant renewal of the poison, nature and art will, I fear, fail to lessen the ravages of this very fearful disease. When the disease takes the form of *phlegmasia dolens*, the disease is not more manageable than that which we have been considering. The treatment should be decidedly antiphlogistic: abundant local bleeding, a position such as will most facilitate the return of blood to the heart, and emollient applications, are the means which have obtained the greater number of cures. Many cases of *phlegmasia dolens* which have resisted other means, have given way to the suspension of the arm by the wrist; and similar means, such as a steep inclined plane, have seemed to produce similar effects in the inferior extremities.

AIR IN VEINS.

Various experiments made on living animals would seem to demonstrate that the injection of air into blood vessels, determines accidents which are speedily fatal.

Since the 17th century, such experiments are recorded by Morgagni, *Epist.* 5, *Sect.* 21, in support of the explanations given by him, as to the cause of sudden death in many cases, where, after death, no appreciable organic lesion was discoverable, but where there was an accumulation of acrimiferous fluid in the heart and great vessels. Wepfer appears first to have discovered that insufflation of air into the jugular of a living animal kills instantaneously. This experiment was repeated by Redi, Van-der-Heyden, and others; they also ascertained that death was as much more rapid as air was more forcibly impelled.

In all animals so destroyed, it was discovered that the ventricles or the auricles were so distended with air, that the experimenters conceived that this extreme distension had prevented the organ from contracting; in the same way that an over distended bladder loses its contractile power.

Langrish (*Physical Experiments on Brutes*, 1746,) called attention to the subject in England; and Chabert recommended it, as a mode of destroying glandered horses, without shedding blood; a practice which has been a good deal followed by veterinary surgeons. Bichat, resting his opinion upon certain of the cases mentioned by Morgagni, expressed his belief, that instead of the heart, the brain is first affected. Nysten demonstrated the error under which Bichat laboured. Now, as to the mechanism by which the introduction of air occurs, much discussion has occurred. If we expose a jugular vein, we observe in it a phenomenon of flux and reflux, isochronous with the movements of inspiration and expiration: after an incision has been made in it, a certain quantity of air may pass into the vessel, and arrive at the right cavities of the heart. At the moment of its introduction, a lapping, gurgling, or whistling noise, is heard. It is possible that the principal cause of the introduction is inspiration, because this noise is usually isochronous with inspiration, and seems in all respects to be modified by it. This may not, however, be the only cause, for sometimes those sounds are more precipitate than the motion of inspiration, and then they appear to be isochronous with the beating of the heart: in this case the diastole of the heart (the right cavities) and more especially of the right ventricle, concur with the dilatation of the chest to produce the effect.

When death has been brought about by these means, we find, usually, a large quantity of air in the right cavities of the heart and in the pulmonary artery. Occasionally the distension of the heart is so great, that the cavities are three times their ordinary

volume: sometimes a certain quantity of air is found in the left cavities of the heart, sometimes in the vessels of the brain. The fact of death occurring with extreme rapidity is rarely witnessed: brute animals will often continue to respire regularly and quietly for many minutes after the opening is made into the vein, and even after a blowpipe is introduced. Usually at some period not commonly exceeding ten minutes, the respiration and circulation become embarrassed, become more frequent, the animal power diminishes, anxiety and agitation are manifested; but even at this time, if we conclude the experiment, the animal soon becomes relieved, and often completely recovers: if, however, the experiment be continued, the respiration becomes more and more laboured, the animal becomes more and more feeble, the sphincters are relaxed, convulsions come on, and death.

The rapidity with which death follows the introduction, seems to vary with the animal, the size, the species, his previous health, his position during experiment, the quality of the air, the quantity, and the promptitude with which it is introduced. Usually the contrast is very great between the extreme rapidity with which death follows, when insufflation is employed, and the comparative slowness by which it is brought about when air is spontaneously introduced. A dog may be killed by a single insufflation in half a minute to a minute: a horse may be killed in five or six minutes, by two or three. Whether this be owing to the force with which the air is propelled, the quantity which may be thus injected, or the quality of the air thus introduced, it is not easy to decide. As to the quantity necessary for the destruction of an animal, the only approximate evidence I know is that furnished by M. Barthélemy, who says, if we push, by a single jet, into the jugular of a horse, seven pints of air, we destroy him in a space of time varying from four to nine minutes. And those furnished by Nysten, from his experiments on dogs, shew that if only a moderate quantity of air be injected, the animal promptly recovers, but if we inject from 70 to 90 cubic inches, death follows with more or less rapidity. Proceeding upon these data, M. Barthélemy concludes, that about thirty ounces of air quickly introduced would be sufficient to destroy a man.

The principal causes of death seem to me to be, the enormous distension of the right cavities of the heart, which prevents the contraction of that organ; the presence of air in the pulmonary artery and in the lungs, rendering the blood viscous, spumous, and unfit to circulate in the pulmonary capillaries; and when the air gets

into the venous system of the brain, possibly the pressure upon that organ.

In the experiments made upon animals, certain means of relieving this condition have been tried: compression of the chest has not seemed to prevent the introduction of air. Nysten thought differently; certainly, by a sudden and forcible compression of the chest and the abdomen, a certain quantity of blood mixed with air may be forced out through the wound; and the aspiration of a syringe, whose pipe is introduced into the vein, may bring out a similar fluid; but we attach no great efficacy to either or both these means.

In applying this evidence of the action of air introduced into the veins of brute animals, to man, we should be very circumspect; because rigorously speaking, the physiological conditions are not the same. Still there are certain applications and inductions which may be legitimately employed. I believe we are justified, upon the faith of the evidence to which we have referred, in concluding from the most pressing induction, that air may be introduced into the large veins, cut during operations practised upon man, in the vicinity of the superior part of the thorax; and maintained open, either by reason of a morbid condition of the tissues, or by any other mechanical or physical cause. Not only is the thing possible, but unfortunately it has been realized in at least half a dozen cases. I might mention nearly forty in which this accident is said to be the cause of death; but to my mind they appear inconclusive. Probably, doubts might be entertained by some persons, with regard to even three of those six, for they are wanting in certain circumstances necessary for inducing conviction.

Of those three cases, one occurred to Beauchesne, one to Dupuytren, one to Castara. In July, 1818, Beauchesne was in the act of removing a tumor from the right shoulder; in cutting through the clavicle, a whistling noise was heard, and the patient died in half an hour from the commencement of the operation. Upon examination, the jugular was found to be cut, the cavities of the heart were empty, the veins of the brain, the aorta, the crural arteries, the inferior cava, contained bubbles of air. Dupuytren, in 1822, was removing a tumor from the superior and lateral part of the neck, when a whistling sound like that of air rushing into a vacuum was heard, and in a few minutes the patient died, having lost very little blood. The right auricle was distended with air. Through the arteries and veins of the trunk, the extremities, and the brain, air was disseminated. Castara, in 1826, while removing a tumor of the right shoulder, and cutting near the axilla, heard a gurgling noise: the

young man became insensible, made two deep inspirations, and died. The right cavities of the heart were distended, the left contained some air; the superior cava and subclavian also contained much of the same fluid. As to the rapidity of death in certain cases, I am bound to admit, that it is not easily explained, for in brute animals air may be passing in for ten minutes or a quarter of an hour without seriously compromising life. To explain so great a difference, it is necessary to suppose either that air acts much more deleteriously upon man than upon brute animals—indeed this would seem to be almost demonstrated—or that the state of exhaustion, in which patients undergoing operation are often found, either from loss of blood or the pain and reaction upon the nervous system, powerfully second the action of the air. Again, the vertical position commonly preserved during operation, may aggravate accidents: nor must we forget that the moral impression produced upon persons under operation, during the time the air is passing in, is an element which should not be neglected in explaining the rapidity with which death occurs.

It is of course a primary and necessary condition, that for the spontaneous penetration of air into the venous system, that tension and dilatation of veins, of a medium calibre, should exist; without this, atmospheric pressure would bring the parietes of the vessel in contact, and the introduction of air into its cavity would be prevented. Now the permanent dilatation of a vein may result from abnormal adhesions by which the vessel is maintained open, or from the hypertrophy of the vascular parietes, which destroys the natural flexibility of the venous tissues. Independently of these causes, accidental in their nature, there are others which are natural and constant. The principal branches of the superior cava, in the vicinity of the heart, have, for the most part, with the different aponeurotic laminae of the cervical region, connections, so that the parietes of these vessels are constantly maintained in a certain degree of tension; and these veins thus form canals which have greater tendency to remain dilated than to collapse. It is, therefore, very necessary to study this anatomical disposition, in consequence of the particular influence which it should exercise upon surgical operations practised at the upper part of the thorax.

If unfortunately the accident should arise, the first step to be taken is to cover the extremity of the vein with the finger, and bring the parts together so as to prevent a further ingress. The other means to be employed are such as should be used in ordinary syncope, but they should be employed energetically and perseveringly.

We cannot rely upon compression of the chest, as suggested by Amussat; nor compression of the abdomen, as recommended by Nysten: we cannot squeeze out the air which has been admitted; neither can I see a case in which it is at all probable you will be able to do what was recommended by Magendie—introduce the tube of a syringe into the wounded vein, and by aspiration remove the air which may be contained in the heart. It is a subject of great difficulty, upon which much time and experiment is necessary; at present, we may say, "*Multa enim pendenda sunt, antequam bene ponas.*"

LECTURES

ON THE

ALTERATIONS OF THE BLOOD.

BY M. ANDRAL.

General and preliminary observations—Importance of attending to the state of the blood—Nature of the alteration which this fluid undergoes—Such change affects its quantity or its quality—Changes of quantity—Phenomena attending plethora and anemia.

IN those sciences which are called natural there is no primitive fact such as may be found in some others. Geometry is based upon the law of gravitation. In our study of the natural sciences, it is sufficient to analyse the facts, to classify, to bring them together, or separate them, as be necessary: for this purpose different methods have been employed. Some, supposing the existence of a primitive principle, endeavoured to arrive at it, and sought for it in the material, or the dynamic, state of life. In pathology, it has been sought for in the solids and fluids; at one time, inexcitability, named also excitability, or the vital forces, was considered as its seat. Others have attempted to study the laws of the vital forces, as they would those of gravitation;—the attempt has been fruitless, for we can find no primitive fact from which the particular ones can be deduced. In the actual state of science, we cannot trace any general fact which will give us a key to all the others, as gravitation gives us the solution of all the facts in geometry.

Many persons at the present day reject any researches on this subject, and merely study the facts themselves; such are the empirics or exclusives, who, seeing the errors of our predecessors, will not inquire into the causes of effects. All those who, at the present day, give themselves up to the study of these sciences, admit a succession of facts drawn from the different systems of fluidism, solidism, &c., and re-

cognise those which have stood the test of ages, while they reject those which are erroneous; and I am willing to admit, that all the doctrines that have swayed the minds of men do contain some one fact or other, although the conclusions drawn from them may have been false. This doctrine is at present much in vogue, and by it we explain one fact by solidism, another by fluidism, and another by vitality. At present every body is eclectic, while twenty years ago it required no small degree of courage to be eclectic, or fluidist, or to maintain that the alterations of the blood had any influence over diseases. I found that the theory of solidism could not explain a great number of facts, and I sought for their solution in the different theories of fluidism, &c., and thus I became eclectic, whilst almost all were still influenced by the doctrines which then prevailed.

We have to study the forces which have been created with matter, and the influence which these forces exercise over it. Are the forces which produce the phenomena in organized bodies identical with those which produce them in unorganized, or bodies inert? Although organized bodies possess functions peculiar to themselves, we are not to conclude from hence that they do not possess properties which belong also to matter in general. We have two orders of phenomena: one produced by laws which regulate matter in general, the other by laws which regulate organized matter. Excitability is a special fact, but phenomena purely chemical and physical also take place in our bodies, as many of them are explained by weight, porosity, &c. We therefore admit two kinds of forces or phenomena in the living body,—one which is peculiar to organized matter, the other which is common with the physical laws. Our predecessors had attempted all that has been discovered within our time, but they were exclusives—some being chemists, others physiologists, others mechanics, hydrodynamists, &c. What marks our era is not the number of discoveries, but that we take into consideration the facts which have been collected in past ages, without being exclusives, chemists, solidists, &c., and resuming the labours of our predecessors, we are enabled to improve upon their ideas by the greater lights furnished to us by the sciences of the day. Philosophical doubt is useful to science, but scepticism is fatal to it. Sceptics, although disbelieving the testimony of others, are very credulous as to what they themselves observe, for it is one of the principles of our mind to search for causes of effects produced, and when we meet with a fact to endeavour to trace it up to its origin. Before the clinics had

afforded the advantage of studying diseases from nature, the student was obliged to acquire his information from books, and thus was thrown into practice without having ever seen those affections which he was called upon to treat. But now that the hospitals have been thrown open, and that clinical instruction gives every facility for studying diseases from nature, the student too often thinks that he may dispense with reading; but let me tell you that there can be no good observation without reading, and the number of facts which any one person can observe can never be sufficient to make him acquainted with medicine. On this account, I strongly recommend you to read both the ancient and modern authors.

I shall treat this year in particular of the diseases produced by the alterations of the blood, and then of those of the nervous system.

The alterations of the blood played an important part in the old systems of pathology. The solids were represented by the containing parts, the fluids by the parts contained, and the movements by the vital forces; the ancient Greeks clung to these opinions, being exclusively and successively attached to the doctrines of fluidism, solidism, and of the vital forces. Galen proved that these different sects should be united into one, as laid down by Hippocrates. During the seventeenth and eighteenth centuries, the humoral doctrines prevailed, but at the beginning of the present they lost ground; their insufficiency being felt, people were obliged to have recourse to solidism, and among the latter is found Bichat, who, although a solidist, was not an exclusive. Pinel attributed every thing to the alterations of the solids: this doctrine prevailed until about ten years ago, when that of fluidism began to revive, and at that period the alterations of the blood, which to-day are duly recognised, were not admitted. Pinel rejected all the helps of chemistry, but this science, aided by the microscope, is now enlarging the field of our observations.

Every thing comes from the blood, and every thing is carried off by it, and as it is of great importance in physiology, so likewise its importance should be considered in pathology; but until this is confirmed by observation, we will not admit its influence into this science. Many theories have been advanced, but few facts have been established. It is very necessary that we should be well acquainted with the healthy state of the blood, before we can decide upon its alterations. We are still ignorant of the composition of the blood, for the theory which yesterday was looked upon as conclusive and convincing is to-day replaced by a new one. Those who

study the microscope see with different eyes; their researches on the blood, like those of the chemists, differing greatly from each other. Another plausible objection which has been raised, is, that the blood which we examine in the cups is no longer the same fluid which circulates in the living vessels: it is not necessary to resolve this problem, for all that is required is to find out if this blood is always the same, and if it is always identical, the alterations which it exhibits, represent those which existed in the living state. History is a prophet come back. Bordeu exclaimed against the chemists, who, by means of their science, explained the vital forces; the systems of chemistry of Kowalle and his contemporaries have been overthrown by that of Lavoisier, and, perhaps, it may come to pass, that the chemical theories which are received to-day will vanish in their turn; for can the chemist pronounce his science to be certain, when so many systems have been subverted? I can shew you many facts in pathology, first established by Hippocrates, and which to-day are received as such, proving that the science of medicine contains many positive facts.

The alterations of the blood are of two kinds—in its quantity and in its quality. This latter is the most complex, as it may be changed in its visible properties, in its density, colour, &c.; which changes may be ascertained without the aid of instruments, but by the aid of the microscope we discover others. Alterations in the chemical properties must also be studied; for although we must admit the insufficiency of chemistry at present, yet it furnishes a certain number of positive facts. The blood of an animal affected with anthrax (*charbon*), although, with all our means of examination, we can detect no alteration in its composition, injected into a healthy animal will cause its death.

Astruc divided the alterations of the blood into three classes.

In the first class he described the alterations in quantity, which may be increased or diminished. The second class, which he subdivided into three orders, comprised the alterations in its qualities.

1st Order.—Alterations in its physical properties, its consistency, thickening, coagulation, &c.

2d Order.—Alterations of the crassamentum and composition of the blood, by means of foreign particles, pus, miasmata, &c.; or alterations in the principles of the healthy blood, in its serum, fibrin, globules, &c.

3d Order.—Augmentation of its salts, &c.

In his third class he described those alterations resulting from a modification in

the motion of the blood, which was either thus affected in its entire mass, or merely in the movements of its globules. This latter question is now attempted to be decided by the microscope.

What forms the subject of our investigation to-day, had also been the study of the ancient teachers.

1. *Alteration of the Blood as to Quantity.*

Any increase or diminution in the quantity of the blood produces a change in its constitution: thus, if it be augmented, the blood becomes richer, and *vice versa*. We can only tell by analogy and reasoning whether the quantity is increased or diminished; and by observing the phenomena which occur when this change takes place, physiology teaches us that the blood vivifies, gives colour, &c., and when we see all its functions increased, the tissues being more coloured than usual, we admit, by reasoning, that the blood which produces these effects is increased.

This condition constitutes plethora, or general hyperemia. If the sanguineous temperament be exalted, a state of plethora is induced. Formerly, four kinds of plethora were admitted.

1. Plethora ad molem, with respect to the mass of the blood.

2. Ad spatium, related to the space, the vessels being retracted, the blood not being increased.

3. Ad vires, the forces of the circulatory system being irregular.

4. Ad volumen vel spuriū, related to the expansibility of the blood, occupying more or less space, depending upon nervous condition, &c.

Some cases occur in which the capillary vessels are more or less dilated, and in which the plethoric state is simulated, as in hysteria, and many other nervous diseases; and the same has been found even where the asthenic diathesis has existed; as also after great loss of blood, and in those cases where sanguineous congestions have been formed in different parts.

Is the density of the blood augmented in plethora? It is often very difficult to tell, by the appearance of the blood, whether it is changed in this character. In the plethoric state it presents a large clot, and its density and consistence are considerable; but this state of the blood may be found in a healthy person, and therefore these appearances do not furnish us with any pathognomonic signs. The blood drawn from plethoric persons, does not, in the great majority of cases, present a buffy coat, which is well formed, whitish, resisting, and of half a line in thickness; and if, after phlebotomy, the blood drawn does furnish a well-marked buffy coat,

it is probable that no plethora exists. Boerhaave thought that the blood of plethoric persons was thicker than that of healthy persons; but of this we have no sufficient proof.

Influences of Plethora on the Constitution.

1st. It may modify the symptoms of disease, and should also produce a modification in their treatment.

2d. It may produce several diseases.

3d. It may in itself constitute a disease.

1st Proposition. — Plethora was looked upon by the ancients as a state of inflammation, or of general reaction. One of the effects of plethora is to produce local hyperemia or sanguineous congestion; but these latter may increase and become developed with the asthenic state, and will only be removed by such means as will cure the latter—as quinine, &c.

Hæmorrhages are sometimes brought on by a plethoric state. The suppression of the catamenia, by producing plethora, may be the cause of hæmorrhages, although these latter are not always connected with such a condition; as, for instance, apoplexy of the brain, which is seldom dependent upon plethora. I think it is a mistaken notion which supposes plethora as predisposing to inflammation; for, out of thirty cases of pneumonia, two are not produced by, or owing to, a plethoric condition. If, out of ten persons exposed to cold, one escape an attack of pneumonia, that one will probably be of a plethoric temperament.

Certain diseases of the skin, such as boils, &c. seem to depend upon a plethoric state; and a cutaneous eruption sometimes appears in those in whom plethora has been induced by a suppression of the menses.

2d Proposition. — There are some morbid conditions in which the secretions are increased, which seem to depend upon hyperemia. Plethora, among other causes, produces an augmentation of the serum; giving rise to active dropsies, in which the vessels seem to be too full of blood, and which are relieved by blood letting; if in living animals we distend the circulatory organs with water, absorption becomes diminished, and the transudation from the vessels increased: some serous exhalations seem to depend upon the quantity of blood in the vessels being increased. Plethoric persons perspire freely and constantly through the skin, and if this perspiration be checked, the skin becomes the seat of a pruritus, and symptoms of fever may shew themselves, which will disappear when the perspiration is re-established: the urine of plethoric persons contains a quantity of uric acid, which forms a deposit of red particles, and their

blood being very rich, we might suppose that nutrition would be greatly increased, but we do not find this to be the case, although the heart is sometimes found hypertrophied. I do not believe, generally speaking, that plethora excludes the formation of tubercles and other morbid productions; but this rule is not without exceptions; if cancer becomes developed in a plethoric person, who is at the same time of a sanguineous temperament, it gradually destroys the state of plethora. Plethora also exercises certain influences over the nervous system in congestions of the brain and of the respiratory apparatus.

Third Proposition.—The plethoric state being exaggerated or increased to excess, may in itself constitute a disease in which all the functions become deranged, and a fever is produced. I am of opinion, that plethora increasing to a state of excess, may cause fever in the same way as it may produce derangement of a single function: the fever thus taking place in a plethoric person, always assumes the inflammatory form, and requires blood-letting. This fever may be symptomatic of a phlegmasia of the heart or the vessels of the circulatory system, or may depend upon the overexcitement of the organs by the blood, which is too rich, and may be designated hyperemic fever; it is short in its duration, and terminates favourably; the state of excitement being calmed by evacuations preceded by perspirations or by epistaxis, or hæmorrhage from the uterus or hæmorrhoidal veins, the blood by these means being diminished in its quantity or richness. Or it may terminate in another manner, the excitation being determined to a particular organ, which henceforth will constitute the predominant lesion: there are few phlegmasiæ which are not preceded by this inflammatory fever, succeeding or produced by an exaggerated plethora.

Causes of Plethora.—It may exist from birth, or become developed without any particular cause. There are some persons who make too much blood, others on the contrary make too little. We are ignorant of the natural causes of plethora: the different periods of life exercise a great influence over plethora: children are exempt from plethora, on account of the activity of their growth; a state of false plethora is common amongst them, on account of the delicateness of their skin, and this condition is styled lymphatisme. When the growth stops at the time of puberty, plethora frequently shews itself, constituting what is called accidental plethora, which may disappear in a short time. Old age seldom falls into a state of plethora: although from certain causes it may exist at this period of life, the plethoric state exists in a direct ratio with

the activity of the functions which produce the blood.

Influence of Digestion.—The more abundant is the formation of chyle, the more likely is plethora to be produced; and it is frequently met with associated with a great increased development of the respiratory apparatus. There are two varieties of old men—one who retain the appearance of youth, and whose lungs resemble those of younger men; and the other, who are decrepit, and whose lungs present enlarged cells, and in whom the organ of hematose is imperfect: persons of a nervous temperament generally have a quick pulse, and are not subject to plethora, and from this circumstance we may infer that the rapid circulation of the blood is not a cause of plethora. The palpitations of the heart, which are met with in plethoric persons, are the effect and not the cause of plethora: if the period at which menstruation begins passes over without the appearance of the discharge, plethora is frequently induced: during the whole period of menstruation it may be produced by any suppression of this secretion, and the cessation of the menses may dispose to it, and it may likewise occur during pregnancy. Plethora shows itself in some individuals at the time of spring; and the acute diseases which occur at this period of the year require to be actively combated by blood-letting.

Anemia.

Anemia is that state which is opposed to plethora, and in which the vessels contain a lesser quantity of blood, which is of a deteriorated or impoverished quality. Some persons bear the loss of a large quantity of blood without falling into this state, whilst in others this condition is produced by the loss of a small quantity. Those of a nervous temperament, and particularly women, do not bear the loss of much blood, and having this in our recollection, when treating their diseases we do not carry our bleedings to the same extent as we would in other cases: hospital patients support bleeding better than those in private practice.

Age considered with respect to bleeding.—We meet with some cases when we must bleed, without taking into consideration the age of the patient. The state of anemia is easily produced in children under the age of six years, by large bleedings. Robust old men will bear large bleedings, but those whose lungs are, as it were, atrophied, and in whom the process of sanguification is feebly carried on, are easily thrown into this state, and large bleedings in them may be attended with the most fatal results. In such cases, the bleeding, if employed to arrest the inflammation,

if pneumonia is the subject, will fail; the bronchial tubes become filled with mucus, and death takes place. This division of old men into these two classes will explain those different results which we find detailed by authors. The more rapid is the abstraction of blood, the more quickly is anemia produced.

In anemia the blood is altered in its physical properties, as well as in quantity. The proportions of water and serum are increased, and those of the fibrine and globules are lessened.

Causes of Anemia.—Some persons, without any cause to explain it, produce an impoverished blood, and present a condition of spontaneous anemia, characterized by paleness of the face, and all the symptoms of debility, without being affected with any organic disease, or having suffered the loss of blood. This state is more frequently met with in women than in men. Is there any difference between anemia and chlorosis? This latter affection is now considered as depending upon the uterus. A man who has lost much blood by hemorrhoids will present all the symptoms of chlorosis. The blood of a chlorotic patient presents the same alterations as that of an anemic person. Anemia produced by an hemorrhage is cured by the same remedies as chlorosis. I look upon chlorosis as a state of spontaneous anemia more frequent among women, and met with not only amongst adult unmarried women, but also amongst married ones, and girls of seven years of age. Anemia may be produced accidentally by hæmorrhoidal discharges, prolonged abstinence, diseases of the lungs, and great efforts and expenditure of nervous influence. About twenty years ago, an epidemic anemia broke out amongst those employed in a mine in the south of France, and all those who were attacked by it presented the symptoms of chlorosis; its causes could never be ascertained, and it is the only case on record of the kind. Anemia may be produced by an unwholesome atmosphere; but the affection thus brought on is of an imperfect form.

Symptoms.—Anemia exercises a great influence over the intelligence, sensation, and the movements of the muscular system.

Effects on the Intelligence.—Delirium sometimes follows large bleedings; the brain being imperfectly excited by an impoverished blood, produces disorders of the intelligence, and the delirium thus produced has been well described by Marshall Hall, who mentions thirty cases which were treated by brandy and beef-tea.

A comatose state, putting on the symptoms of inflammation of the brain, may be connected with a state of anemia;—

when persons are recovering from an illness which has brought them to the verge of the grave, and after great debility are beginning to retrieve their strength, their intelligence becomes disordered, and a real state of mania becomes developed. [A case was related of a woman recovering from peritonitis, who was affected with delirium during her convalescence, which was prolonged for six months, at the end of which time her forces having returned, her reason again became sound, her blood at this time being produced richer in quality.]

Effects of Anemia on Sensation.—In a number of cases the sensibility increases as the blood becomes impoverished: the skin becomes more irritable and sensible; sounds strike painfully on the ear, odours are disagreeable, and light hurts the eyes. These symptoms disappear when the state of anemia ceases. Total abstinence prolonged brings on anemia, with total loss of the sight, preceded by a state in which the sense of vision becomes exalted. This kind of amaurosis is followed by death, and dissection discovers no lesion of the brain, which is merely found paler than natural. [Case cited in which there was loss of sight produced by a fright, which caused a shock to the nervous system.] Vertigo, headache, singing in the ears, &c., are produced by anemia, and in some cases it is impossible to distinguish the symptoms of anemia of the brain from those depending upon hyperemia of that organ. [Case related of a man who had been repeatedly bled for symptoms which were referred to a cerebral congestion; in consequence of this treatment, he became very nervous, pale, and sunken; his sight became affected, his digestion deranged, and his functions disordered. By the gradual exhibition of tonics all these symptoms were in time removed.]

Contractility affected by Anemia.—Great weakness of the muscular system in chlorotic females is often the first symptom of anemia, and this debility seems to depend upon the blood containing less fibrine. We sometimes meet with cases of convulsions in which the muscular system is in a state of exaltation. Animals who die of hemorrhage die convulsed, and in children convulsions are produced by leeches or by chronic disease, and lying-in women are often thus affected after floodings. Young females, who are pale and chlorotic, are often affected with chorea. Subsultus tendinum is another example. These are all proofs that convulsions exist in connection with anemia, or an impoverished condition of the blood.

[Case of tetanus cited, which came on after an hemorrhage.]

ON THE
CAUSES, SYMPTOMS, AND TREAT-
MENT OF SUPPRESSION OF
URINE.

By JOHN CHARLES HALL, F.L.S.

Fellow of the Royal Medico-Botanical Society,
and Member of the Royal College of Surgeons,
&c. &c. &c.

[For the London Medical Gazette.]

Aliter vitium vivitque tendo.

MASON GOOD, in his Practice of Medicine, designates this disease paruria inops. Dr. Elliotson, in his lectures (MEDICAL GAZETTE, vol. xii.), speaks of it under the title of ischuria; and Dr. Willis has well described it by the name of anuria, or anuria apyretica: in truth, so many are the titles given to it, so obscure are the symptoms marking its approach in the first instance—aye, even its existence, in the earlier stages—that we may not inaptly observe, with Virgil, that “the disease lives by being concealed.” The disease is not one of very frequent occurrence. Dr. Elliotson remarks, “he has only seen one case,” and that occurred after the patient had taken a quantity of corrosive sublimate by mistake: by proper treatment the man recovered, but, after some days, was attacked with anuria, attended by hemiplegia, and that drowsiness which is always a symptom after suppression of urine has continued for some time. From this we may infer—that is to say, from the apoplectic symptoms ushering in death—the urine is re-secreted into the ventricles of the brain; but in the case at present under consideration, nothing of this kind was discovered; “there was not only no urine in the head, but no excess of fluid either in or upon the brain;” a result for which the doctor was evidently unprepared.

Dr. Bright, in his valuable Researches into Diseases of the Urinary Organs, remarks, “that in cases of granular degeneration of the kidneys, total suppression of urine but seldom occurs.” There is, however, no doubt but that various states of the system, both in health and also in disease, have an effect upon the secretion of this fluid, which I regard as composed of certain elements, the longer continuance of which in the blood than natural is always attended by disease, and the total suppression of their

elimination, by death: the last stages of the patient's life being marked by symptoms which denote an affection of the brain. Respiratory and intestinal exhalations, as well as cutaneous transpiration, more or less influence the functions of the kidneys. Copious dejections from one or more of these surfaces diminish the quantity of urine, and the opposite states never fail to produce a contrary effect. In fever, in small-pox, after injuries and surgical operations, we have (more or less, as the case may be) a diminution of the secretion of urine. Again, after injuries of the spine in the region of the kidneys (or tubercular disease of the cord), we have frequently retention of urine, with considerable febrile excitement. But besides an inability of voiding the urine, Sir B. Brodie has frequently pointed out a marked diminution of the quantity secreted. In some cases the urine first secreted, although of an acid quality and free from mucus, has a very offensive odour; in other cases I have remarked its peculiar acid nature, its opaque appearance, and yellow amorphous sediment. I regard, however, the most common change to consist in the peculiar ammoniacal smell, and the deposit of a large quantity of adhesive mucus: the urine, when tested with reddened litmus or turmeric paper, is found to be very alkaline. After some time, phosphate of lime, secreted by the inner coat of the bladder, is blended with the mucus, which is tinged with blood. Such a state of things may be produced in three or four days after the accident, or they may not come on for a week: in one case, I remember, it was nine or ten days after the injury had been received, that they were apparent. I am not aware that one part of the spine, when injured, is more liable to produce them than another. In fatal cases they remain to the last; in others which recover, they perhaps go on for three or four weeks. There is another peculiarity, also, to which my attention was first directed by that justly celebrated surgeon (during the time I was his pupil, at St. George's Hospital) Sir B. Brodie, which consists in the variation which takes place in the state of the urine; to-day it may be alkaline, depositing adhesive matter; the next, we may find it clear and acid, and the day after alkaline again. Suppose, however, that the spine becomes injured, and that

very little disturbance at the time takes place—so little, in fact, that it may be overlooked; after some days, the patient is attacked with paraplegia, followed by gangrene of the nates and retention of urine; but perhaps after a week, or even a longer period, the quantity secreted is diminished, and at length ceases altogether, when fatal coma terminates the existence of the sufferer—terminates an existence deplorable in the extreme. The peculiar suppression of urine in cases of malignant cholera is well known to all who have attended cases of that singular and fatal disease. But independent of acute disease—independent of any derangement that is apparent in the structure of the kidneys—their secreting office is completely suspended. This morbid condition constitutes the disease which Dr. Willis has named anuria; said by him to terminate in coma in four or five days, and in death in a few days more. I am of opinion, however, that in complete suppression of urine, death takes place in a much shorter period; in some cases, in less than forty-eight hours. All cases end in coma; some with, others without, convulsions, but all have evident symptoms of apoplexy.

Notwithstanding this disease is said to be of “rare occurrence,” I am inclined to think that such is not the case; the symptoms are so masked that the patient may die without the true nature of the complaint being discovered; nor am I aware that, until late years, the profession have very particularly directed their attention to it. Suppression of urine may be divided into two stages:—1st, when the suppression is partial, and 2dly, when it is complete.

1st. Cases in which we have a Partial Suppression of Urine.

Such cases are far from unfrequent. A patient exposes himself to a cold atmosphere—remains loitering about in his garden, for example, on a cold November day. In the evening he complains of having taken cold, creeps to the fire, and has frequent rigors. He retires to bed; his skin is hot and dry; his urine scanty and high-coloured; his tongue, the next morning, is coated; perhaps the bowels are confined. This scanty secretion of urine not unfrequently continues for some days, although the patient feels better, having been relieved by copious evacuations from the bowels and continued perspiration. Dr. Parr

relates a case in his own practice in which no urine was secreted for six or seven weeks; and the case of a boy of seventeen is mentioned by Dr. Richardson who had never made water from his birth, nor had felt the least uneasiness on this account, being healthy, vigorous, and particularly active. Haller also has given us some account of a case (Bibl. Med. Pr. ii. p. 200,) that lasted for twenty-two weeks. He does not, however, give it upon his own authority; it was probably related to him by another, and, I think, is little to be depended upon: it is folly to suppose that the constituent principles of so important a secretion as the urine can long continue in the blood—can long float in the system, and load the blood, without the greatest danger. “The outlet,” (says Dr. Mason Good,) “at which these are separated and discharged is not always manifest, and hence they sometimes appear not to be separated at all.” If, however, a minute observer—a practical and accurate pathologist, makes the examination, the vicarious channel will always be detected.

The two great outlets which serve instead of the kidneys are the bowels and the skin. Dr. Parr informs us that, in the case just quoted, there was a profuse sweat; he does not, however, give any account of the state of the bowels. In Dr. Richardson's case, he admits that the young lad laboured under constant diarrhœa. Dr. Samuel Arnold, in the “New England Journal of Medicine and Surgery,” mentions the case of a young woman who had a retention of urine for two years, and through the integuments of whose lumbar region a fluid like urine escaped. On one occasion she was not relieved by the catheter for seventy-two hours, when a fluid, like urine, was discharged, first in drops, and then in a larger quantity from the right ear. This patient vomited a fluid like urine, and, on one occasion, a fluid oozed from the navel. The fluid was on all occasions found to contain urea. During a period of several years, whenever the discharge diminished, (that is, when the kidneys refused to secrete), the patient was attacked with delirium, and occasionally with violent spasms like those of opisthotonos. M. Andral infers that the blood “contains, in variable proportions, the elements of all the secretions; that, under ordinary circumstances, these elements are separated from the circulation only by those organs whose special

structure is adapted to bring about such separation ; but, under particular states, these elements may be separated from the circulation by other channels than those regularly intended for the purpose ; not, indeed, in the condition of perfect secretions, but in a more simple form, containing the elements of such secretions."

I shall not here proceed to speak of the treatment necessary in cases where we have only a partial suppression of urine, as that will be best considered when we examine—

2d. *The Symptoms and Treatment of complete Suppression of this Fluid.*

The great and urgent danger of this complaint was first made known by Sir H. Hallford, who has communicated some very valuable observations upon the subject.

CASE I. — "A corpulent and robust farmer, of about fifty-five years of age, was seized with a rigor which induced him to send for his apothecary. He had not made water it appeared for twenty-four hours ; but there was no pain, no sense of weight in the loins, no distension of the abdomen, and, therefore, no alarm was taken till the following morning, when it was thought proper to introduce the catheter, and none was found. I was then called, and another inquiry was made in the afternoon by one of the most experienced surgeons in London, whether the bladder contained any urine or not, when it appeared clearly that there was none. The patient sat up in bed and conversed as usual, complaining of nausea, but of nothing material in his own view ; and I remember his friends expressed their surprise that so much importance should be attached to so little apparent illness. The patient's pulse was, at times, slower than usual ; at others, the patient was heavy and oppressed. I ventured to say, that if we did not make the kidneys act, he would soon become comatose, and would probably die in the following night, this being the course of the malady in every other instance which I had seen. It happened so : he died in thirty hours after this, in a state of stupor."—(*Vide Med. Trans.* vol. vi.)

Since the above was written, I have read Dr. Baillie's valuable work, who appears to bear me out in the division here made between cases where the discharge is altogether wanting, and others in which it is evident that a small quantity is secreted ; for he observes, "here

there is a great difference in the hazard of a patient's situation, whether the kidneys separate a very little urine, or none at all : in the first case he gradually recovers ; in the second, very rarely."

The symptoms of a total suppression of urine are frequently very obscure. The disease often is far advanced before the surgeon is aware of it ; the patient often may be going about his work in the morning, and, in a short period afterwards, be dead. Mr. Campbell has recorded three very interesting cases in the *Lancet*. The first, of a stout man, somewhat above sixty. He found him feeding his cattle out of doors, thinking little was the matter. On introducing a catheter, no water was found in the bladder. On being more closely questioned, he complained of some pain about his back. The next day he died comatose.

From the fatal character of this disease, it is of great importance to detect its approach in the first instance. It may be inflammatory, and then we have symptoms of nephritis. But the case is seldom so clear as this. You find a man following his usual occupation : he sends for you to draw off his water ; and you discover none in the bladder on the introduction of the catheter. There is a dull uneasy sensation about the loins ; a feeling of oppression at the pit of the stomach ; a disinclination to move from place to place ; a loathing of food. These symptoms are followed by rigors, pain in the head, and drowsiness, ending in coma and death.

The effects, then, of a suppression of urine consist in a declining energy and a growing torpidity in every function, clearly showing that the brain is directly weakened and rendered incapable of supplying nervous energy. Again, says the writer before quoted, "it is not difficult to account for these effects, since they naturally follow from the blood being overcharged with that excess of azote which it is the office of the urine to carry off : the destructive power of this agent is known to every one, as is also its further power of increasing the "coagulability of the blood." M. C. Chossat has made some highly interesting experiments (to which I must refer the reader), to decide whether the blood of persons afflicted with anuria be loaded with azote ; but this is a question I cannot take upon myself to give an opinion upon ; we can regard nothing

concerning it as certain until proved by chemical experiment. Suppression of urine may of course be either functional or arise from some organic disease of the gland itself: the symptoms, however, do not vary in either case, and death takes place, according to my experience, in exactly the same manner. I remember attending a case of organic disease of the kidneys, with Messrs. Carriek and Pollock, of Kensington, in which for the last week no urine was secreted.

CASE II.—Mrs. D—, of Newland Street, Kensington, was attacked about six months ago with pain in the hip and loins; pulse quick; urine scanty and high coloured. Notwithstanding the treatment adopted she got gradually worse.

October 1st, 1837.—I again saw her: the urine was now fetid and of a dark colour, often containing long strings of blood: she complained of great pain in the loins, which would not allow her any rest night or day. These symptoms continued until the last five or six days of her existence: her headache then increased; the urine ceased to be secreted; none was passed, nor did the catheter detect any in the bladder; she now became comatose, and died on the 14th of October. Twelve hours after death, I assisted Mr. Pollock in making a post-mortem examination: we found both kidneys diseased, particularly the right, which was one fungoid mass.

My attention, however, has been more particularly directed to this complaint, by the following interesting case, in which there was for many hours a total suppression of urine, yet the man recovered, and is now enabled to attend to the duties of his station.

CASE III.—A short time ago, when in the country, I was called upon to attend Joseph Lambert, æt. 27. He is rather below the middle height, thick-set and stout; his neck is short, his complexion florid: he is under-game-keeper to Earl Spencer, and often exposed to cold and wet.

March 18th, 1840.—He called upon me this morning, and complains of pain at the pit of his stomach; his bowels are relaxed, which he supposes to arise from eating a quantity of new bread last night, and drinking for the last week past more ale than usual; tongue moist; pulse 72; urine high coloured (but does not make less than usual); no headache; has not been of late ex-

posed to cold or being wet; “would be quite well if it were not for the dull heavy pain in his stomach.”

R. Ol. Ricini, ʒi.; Tr. Opii, ℥xij. statim.

He came to me again in the evening, saying, “he was no better;” the bowels had only acted once slightly, since the oil was exhibited: does not think the pain and uneasiness quite so severe as in the morning.

R. Ext. Colocynthis, gr. viij.; Hydrarg. Chloridi, gr. ij. M. Ft. pil. ij., statim sumendæ.

10 o'clock, P.M.—Has sent to say that he is much better.

19th.—I called to see him this morning at nine o'clock, and found him walking about in great pain; his face much flushed; tongue coated; pulse 90, quick and full. He had felt better till this morning: about seven o'clock, feeling uneasy, he got up to make water, and could only void a few drops: has not passed any urine for the last eighteen or twenty hours: upon placing the hand above the pubes it was at once evident that the bladder was not distended: a teaspoonful of very acid urine (all he had passed) was shewn to me. The true nature of the formidable disease we had to contend against was now apparent, and the introduction of the catheter confirmed my worst fears; not one drop of water came away. Upon examining him more closely, he said the pain in the loins was at times very severe; this was succeeded by a dull heavy continued uneasy sensation not amounting to actual pain—to use his own words, “as though the small of his back was half broken;” the eye was dull and heavy, the pupils considerably dilated; he complained also of slight drowsiness and pain in the head: “would go and get some sleep, as he thought bed the best place for him.”

V.S. ad ʒxvj.

The blood drawn was dark, thick, and tar-like; since the bleeding, has had a motion, which is pale and watery, the secretion of bile being evidently diminished. He was ordered to drink freely of linseed tea, to put his feet into warm water, to have a warm bath as soon as possible, and not to think of leaving his bed; the feet being cold, mustard poultices were applied to them.

R. Hydrarg. Chloridi, gr. viij.; Ol. Tigilii, ℥iv.; Ext. Hyoseyami, gr. iv.

Misce et divide in pil. iv. Sumat 1, quaque tertia horâ.

R Sodæ Sesquicarbonatis, ʒi; Pulv. Potass. Nitratis, ʒij; Tr. Hyoseyami, ʒij.; Tr. Scillæ, ʒj.; Tr. Lyttæ, ʒj; Mist. Camphoræ, ʒvss. M. Capiat coch. larga duo quaque quarta horâ.

R Ol. Terebinthinæ, ʒss.; Spir. Camphoræ, ʒj.; Lint. Saponis, ʒss. M. Fiat embrocatio, lumbis applicenda.

This was rubbed upon the loins frequently during the afternoon.

3 o'clock, P.M.—The medicine has produced two watery evacuations; complains of much pain in the head, and a dull heavy pain in the loins; pupils slightly dilated.

6 P.M.—Pupils much dilated; complains of more pain in the head; answers questions in a sharp quick manner, and is evidently becoming delirious. Wonders why I come to see him so often.

12 o'clock.—No better; has had two more evacuations, but has not passed any water. I now left him for the night, with directions to be called if any change for the worse took place.

20th, 9 A.M.—Has passed a bad night. Face flushed; pupils still dilated; complains of great thirst; the skin is still hot and dry; pulse 80, slow and labouring. I introduced the catheter, and drew off about two ounces of water—all that had been voided for forty-two hours.

R Pulv. Jacobi, gr. iv.; Hydrarg. chloridi, gr. ij. M. Ft. pulv. statim sumendus.

R Spir. Junip. ʒij; Muc. Trag. eo. ʒiv; Tr. Hamuli, ʒij; Magn. Sulphatis, ʒi; Aquæ, ʒviiss. M. Capiat. coch. ij. ampla quâque 4ta horâ.

12 o'clock.—Repet. Pulv. Jacobi, gr. vi. To drink freely of warm linseed tea; to put the feet into warm water; to keep the head cool. The bowels have been very freely opened.

9 o'clock, P.M.—Decidedly better; skin moist; pulse 72. Had made about three ounces of water since morning.

R Pulv. Ant. Potass. Tart. gr. i.; Magn. Sulphatis, ʒij; Tr. Lyttæ, ʒss; Syr. Tolutani, ʒss; Aquæ. ʒvss. M. Sumat Coch. ij. ampla quâque secunda horâ.

21st.—The only food he has taken since I was called to attend him has been linseed tea. This morning he is much better; less pain in the head; no pain in the loins; skin moist; pulse 72. Bowels well opened during the night; the secretion of bile evidently increased. To continue the mixture containing the

antimony. He had passed since my last visit about ten ounces of water.

22nd.—Improving. Still complains of a dull heavy pain in the loins; urine scanty, and high coloured.

23rd.—Much better. No pain in the loins; the urine gradually increasing in quantity. Has taken to-day a small bit of toast, the first solid food since he became ill. The pain in the head has quite left him.

R Magn. Sulphatis, ʒi; Potass. Bi-tartratis, ʒss; Spir. Eth. Nit. ʒij; Infusi Sennæ, ʒvi. Capiat coch. ii. ampla nocte manequæ.

R Hydrarg. Bichloridi, gr. i; Ext. Cornii, gr. x; Camphoræ, gr. viij. M. Ft. pil. viij. Sumat ij. hora somni omni nocte.

25th.—Much better. To take one ounce of castor oil when the bowels become confined.

I know of no other symptoms that need be recorded. He got daily better; is now able, as before stated, to attend to his duties, and to support a wife and young family.

CASE IV.—Mr. W. H—, æt. 40, a farmer, of rather full habit and of large stature, but a very temperate man, called some time ago upon my friend Mr. R. Cook, surgeon, Gainshorough, having walked a distance of nearly five miles. He complains of being "generally unwell;" the bowels are confined; has not passed any urine yesterday, or during the night; the pulse is slow and full; the bowels are confined. On passing the catheter, the bladder was found to contain only about two tea-spoonsful of urine.

V. S. ʒxx.; calomel, and saline aperients; an embrocation to the loins.

May 5th.—Bowels freely opened; pulse the same as yesterday; has passed a small quantity of urine.

7th.—Better in every respect. He got gradually well, but never was able to void a natural quantity of urine until he remained some time at Buxton, making frequent use of warm baths. He never had any of the pain, or sense of weight, in the loins, that I have described; in truth, so little did his malady appear to affect him, that his friends generally laughed at the fears of his medical attendant. The case, however, I regard as one belonging to the first division of my subject.

Lastly, we have to examine—

The Treatment of Suppression of Urine.

In our treatment of disease, we ever learn a lesson from the efforts made by nature to repair the injuries that disease or accident has made. Here, too, we may take a valuable hint from her; for as the excretories of the skin and kidneys are continually assisting each other in almost every possible way, we must endeavour, first, to excite the former, by active diaphoretics, to take upon themselves (for a time at least) the office of the latter, and thus carry off the urine that should be discharged by the kidneys; secondly, we must endeavour to restore the kidneys to their usual natural action by diuretics and saline purgatives. The most useful I have already endeavoured to detail in the treatment of Lambert's case. Digitalis has been recommended, but I am inclined to think that it is of little use; and if at all so, only when combined with tincture of cantharides, or some other diuretic.

Kensington, April 9, 1840.

CASE OF TRANSPOSITION OF THE VISCERA,

*Accompanied by imperfect Development of the
Spleen and Uterus.*

BY JOHN THURNAM.

[For the London Medical Gazette]

Two cases of transposition of the viscera having recently been published by Mr. McWhinnie, in the MEDICAL GAZETTE, I have thought the following case might, at this time, be read with some interest; especially as it unites in itself the two rarer peculiarities which occurred in Mr. McWhinnie's and Mr. Curling's cases respectively. I allude to the uncommon course of the inferior cava, and to the antero-posterior transposition of the duodenum and arch of the colon. I may observe that the case is also peculiar from the stomach and spleen not participating in the lateral transposition.

Complete lateral transposition of the Vascular System—Partially lateral and partially antero-posterior transposition of the Organs of Digestion—Imperfect development of the Spleen and Uterus—Long-standing Asthma—Chronic Pneumonia, ending in general Dropsy and Death.

Ann Bunce, aged 37, of short stature, delicately made, and with a very weak voice, was admitted into the

Westminster Hospital, under the care of Dr. Burne, February 13th, 1838. She had been asthmatic for many years, and reported that all her sisters were asthmatic. During two years previously, her general health had been bad; and for six weeks she had been much worse, suffering from severe dyspnoea and other symptoms of diseased lungs. Her feet began to swell about the time of her admission. The face, and especially the lips, were of a deep violet hue, and bloated; the surface was cold; there was oedema of the ankles, gradually spreading to the legs, and in a slight degree to the hands. Pulse very frequent, small, and weak, but regular and equal. There were dulness on percussion, and absence of the respiratory murmur over the region of the thorax, especially on the left side. The murmur was louder than normal in the upper part of the chest, especially on the right side. There were no abnormal murmurs of the heart, the impulse and sounds of which were very feeble. Attention, however, was chiefly directed to the state of the lungs; so that the region of the heart was not so carefully examined as it should have been. Dr. Burne (who, however, did not, in consequence, suspect any transposition of the heart) subsequently informed me that his notes, as to the state of this organ, were in these words—"heart's action distinct, and diffused towards the right side." She gradually became worse, and died March the 8th.

Dissection, 42 hours after death.

1. *Pathological changes.*—The right pleura was nearly free from adhesions; the left was adherent nearly throughout, but most firmly so over the lower lobe of the lung, and between that and the diaphragm and pericardium. The right lung, superiorly and anteriorly, had its air-cells evidently dilated, and a portion of the lower lobe likewise presented a similar condition. Posteriorly, this lung had lost its normal elasticity, and was in a state of general congestion. The upper lobes of the left lung were still more congested, and the whole of the lower lobe was in a state of very decided hepatization; which here and there only appeared to be passing into diffused suppuration. The bronchial tubes were loaded with viscid grey mucus. The heart was of more than full size for so small a subject, and weighed 8½ ounces, avoirdupois. The

anterior (pulmonic) ventricle was hypertrophied and dilated: excepting some scutiform thickening of the aortic valves, and some yellow spots in the mitral valve, and likewise in the aorta, which could not materially have affected the function of the organ, the valvular apparatus of the heart was normal. The arterial duct was quite pervious, towards the aorta, and its pulmonic extremity had only been closed by the delicate lining membrane, which appeared to have been ruptured in the centre before death; perhaps in consequence of the hypertrophy of the right ventricle, and the obstruction to the circulation through the lungs. There was "hepatic-venous congestion" of the liver: the kidneys were small, granular, and of a greyish colour.

2. *Congenital malformations.*—There was an almost universal transposition of the viscera.

a. *The circulating system.*—Upon removing the sternum, the bag of the pericardium was seen on the right side; and the apex of the heart was under the right mamma. The pulmonic ventricle was almost completely anterior, though if any thing inclined to the left side: its auricle was situated more directly to the left side, and received the superior vena cava, at its left upper angle: the relative length of the venæ innominatæ were reversed. The systemic ventricle was, with its auricle, directly posterior. The appendage of the latter was altogether concealed by the pulmonary artery, which occupied the right upper corner of the pericardium, and appeared somewhat dilated and twisted. The ascending aorta, which was of small size, rose up between the vena cava and the pulmonary artery. The arrangements of the internal structures of the heart corresponded with the traversed position of the cavities. The opening, in the pulmonic auricle, of the vena cava hepatica, which took the place of that of the cava inferior, was guarded by a delicate Eustachian valve. In addition to the usual coronary vein, and its Thebesian valve, there was a small coronary vein, which entered the auricle separately, and was also protected by a lunated fold of endocardium, directly in front of the oval hole, the valve of which was completely closed. The ascending aorta gave off the coronary arteries as usual: the arch was directed from left to right, and ended in the descending aorta on the right of the dorsal spine: it gave off, first, the

brachio-cephalic, which divided into the left carotid and left subclavian arteries; secondly, the right carotid; and thirdly, the right subclavian arteries. The relations of the right and left recurrent nerves were, that of the former with the termination of the aortic arch, and that of the latter with the left subclavian artery. The calibre of the termination of the aortic arch was much narrower than that of any other portion; but, after receiving the arterial duct, the opening of which was the size of a large crow-quill, the top of the descending aorta, for a small extent, became dilated in a fusiform manner; so that its calibre became increased by about one half. The descending aorta having entered the abdomen through the right foramen of the diaphragm, continued its course on the right side of the lumbar spine, and, after giving off the usual branches, bifurcated into the common iliac arteries. The vena cava inferior lay on the left side of the vertebral column; the relations of the right and left renal veins with the aorta, of course being reversed. The inferior cava did not, as usual, pass through the notch in the liver, so as to receive the hepatic veins, but entered the thorax so as to take the position of the azygos vein on the left side of the spine. It finally opened into the superior vena cava about an inch and a half above its termination in the auricle, or at the point where that vessel usually receives the azygos vein. The vena cava hepatica entered the thorax through the central foramen of the diaphragm.

b. *The organs of digestion.*—The œsophagus entered the abdomen as usual. The stomach was placed nearly vertically in the left hypochondriac and umbilical regions, and was furnished with a very short epiploon, the laminae of which did not receive the transverse arch of the colon. The course of the duodenum was apparent, without any dissection, in consequence of a curious antero-posterior transposition of the large and small intestines. This intestine first descended nearly vertically for an inch and a half on the left of the spine, which it then crossed, and, after ascending for a like extent, it received the biliary duct, and then turned forward and became continuous, in the right hypochondriac region, with the jejunum. The pancreas was situated quite superficially between the duodenum and the stomach: it had a short

roundish form. The small intestine was but imperfectly developed, scarcely measuring more than twelve feet in length. The cæcum was very large and loose, had its usual appendage, and was situated in the left iliac region. After the colon had ascended in the left lumbar region, it was lost sight of, in consequence of its passing behind the duodenum and root of the mesentery, by which the transverse arch was bound down over the aorta and vena cava: finally, the descending colon and sigmoid flexure occupied the right lumbar and iliac regions. The large lobe of the liver, with the gall bladder and lobulus Spigelii, were in the left hypochondriac region; the small lobe in the left. Behind the stomach was a round spleen, the size of a small apple, and, accompanying it, were five supernumerary spleens, the size of walnuts and filberts, which grew, as it were, from the branches of the splenic artery something like a bunch of grapes. The stomach and the spleen were the only azygos organs which were not transposed.

c. Reproductive system.—The uterus, externally, was of its normal form; but, when cut into, it presented a distinct bilocular cavity.

Retreat, York, April 2d, 1840.

CASE OF GLANDERS.

To the Editor of the Medical Gazette.

SIR,

As the following case is of some interest, being connected with that of the man who lately died of glanders in this hospital, should you deem it of sufficient importance, I shall feel obliged by its insertion in your valuable journal.

I take this opportunity of mentioning, that the cases were under the care of Mr. Stanley, for whom I had the pleasure of dressing, and with whose kind permission I have sent them. It is unnecessary to enter minutely into detail, but the leading circumstances of the case are the following:—

Jane Love, æt. 42, on the third or fourth day after the death of the man John Smith, upon whom she had been attending, perceived a "hard lump" near the left axilla, which was painful, the pain extending down the inner side of the arm. She, however, took so little notice of this as not to mention the circumstance to any of us. On the Saturday evening (March 21st), being the

sixth day after the man's decease, the pain in the arm increased, and an inflammatory blush appeared on it; this, however, she considered to be nothing more than a slight attack of erysipelas, which continued, however, to extend, and on the Sunday morning presented the following appearance:—The anterior, posterior, and inner aspects of the arm, from the axilla down to the elbow, appeared to be the seat of an extensive phlegmonous inflammation, of a brick-red or dusky hue, and limited by a well-defined and elevated border. The swelling was indurated, very tender on pressure, and on its surface could be seen several small elevations, a livid patch about the size of a shilling in the neighbourhood of the axilla, and close to this a large irregularly-shaped vesicle, containing a yellow viscid substance at the bottom, and a clear limpid fluid floating above. The woman, who was of a plethoric habit of body, had an anxious countenance, rapid pulse, dry and furred tongue, which was red at the tip and edges, and accelerated breathing; complained of great thirst and a deep dull aching pain over the situation of the eye-brows. Stated that she had had several attacks of chills and heat alternating with each other, and had scarcely a wink of sleep the two preceding nights. Thirty leeches were applied to the arm, which gave almost immediate relief. The member was then enveloped in a linseed-meal poultice, and the usual antiphlogistic regimen enjoined.

On the next day expressed herself much better; the arm less painful; tongue moist and cleaner. Two incisions were made in the arm; the subjacent tissue was hard and brawny; no pus flowed from the wounds, merely blood mixed with a small quantity of serum. On the following day no discharge of pus from the wounds; the parts shewed no inclination to take on healthy action, but the inflammatory redness had crept down the elbow to the fore-arm. The tongue was dry, brown, and chapped; pulse rapid and deficient in power; countenance anxious. As it was now considered necessary to support the system, she was ordered strong beef-tea and sesquicarbonate of ammonia, in five-grain doses. This for a time had the desired effect, the patient expressing herself as better, the pulse becoming less rapid, with more power, and the tongue in a

better condition. This state, however, did not continue; no suppuration had yet taken place from the incisions; there was no tendency in the parts to take on healthy action; an erythematous blush appeared on the upper part of the chest and about the neck; several red and purple spots, about the size of a split pea, were seen on the left mamma, and between it and the shoulder; the patient complained of great thirst, and was constantly calling out for drink. The inflammatory process gradually extended down the forearm to the wrist and upwards, over the shoulder, involving the side of the neck and upper part of the back, and extending as far round as the shoulder of the opposite side. She gradually passed into a typhoid state, refused all nourishment except a little wine and water, grew weaker and weaker, difficulty of breathing came on, and she sank on the morning of the 30th instant.

The functions of the sensorium were affected early in the course of the disease, a low muttering delirium being present. There was also great dread, on the part of the woman, of having taken the affection from the man upon whom she had been attending.

Post-mortem Examination.—The affected arm was infiltrated with pus; purulent deposits were also seen between the muscles taking the course of the vessels, and extending up to the side of the neck and front of the chest; but the veins were free from deposits, and appeared healthy: numerous small collections of pus were seen in the texture of the muscles on the anterior part of the thorax; the integuments of the fore-arm were livid, and the subcutaneous and adipose tissues infiltrated with a sero-purulent fluid. The mucous membrane lining the larynx, trachea, and bronchi, was highly injected. No unnatural appearance was seen in the parotid or submaxillary glands. There were no adventitious deposits in any of the viscera; the spleen was of its natural size, but softened in texture. The shoulder-joint of the affected side presented no unnatural appearance when cut into.

That the foregoing was a case of absorption of poison into the system, may, I think, be fairly presumed from the following circumstances, namely:—the constant attendance upon the man who was labouring under a contagious disease, the nurse, at the time, having

several abrasions on the hand of the affected side, and the great liability of poisonous matter coming in contact with these abrasions during the performance of her necessary duties: the appearance of the symptoms just at this particular period, namely, within a few days of the man's decease, the aspect of the affected parts, and the history and progress of the case (which last I have not fully entered into, for fear of occupying too much space,) were something more, I think, than an ordinary attack of phlegmonous erysipelas; the great dread of the patient, that she had poisoned her arm, is also not to be lost sight of; the greater frequency of phlegmonous erysipelas occurring in consequence of local irritation, and the comparative rarity of the affection arising solely as a constitutional disease; and, lastly, the tendency of dissection or other poisoned wounds to produce this form of inflammation.

I think, therefore, there can be very little doubt as to the propagation of disease in this instance; at any rate, there can be no doubt as to the necessity of great caution on the part of nurses or others attending upon persons labouring under farcy or glanders. We have lately been informed that the propagation of this disease from one human subject to another has been ascertained in Paris by Breschet. That it is communicable by inoculation from the human subject to the horse and ass has long ago been established by Dr. Elliotson and other pathologists.—I am, sir,

Your obedient servant,

J. R. BRUSH,

Dresser, St. Bartholomew's Hospital.

March 31st, 1840.

P.S.—It may be worth while to mention that I inoculated three kittens with the matter taken from this woman's arm; two whilst she was living, and one after her death; that the kittens appeared to have nothing the matter with them till the punctures were nearly healed, when they were affected in an extraordinary manner, losing the use of their limbs, and appearing to labour under the influence of some poison absorbed into the system; one of the kittens had also a discharge of a thick yellow matter from the eyes; the mother also appeared to be affected, and lay snuffling and sneezing, and refused all nourishment for three days. The animals now being considered unsafe, they were destroyed.

REAGENTS FOR THE ALKALOIDS.

To the Editor of the Medical Gazette.

SIR,

I BEG to inclose you the copy of a paper which, at the request of Professor Buchner, I have just forwarded for publication in his monthly journal. As our present knowledge of re-agents for the alkaloids is limited, I trust that the following remarks may be interesting and useful.—I am, sir,

Your obedient servant,

GEO. KEMP.

15, Kaufinger Strasse, Munich,
April 1st, 1840.

To Professor Buchner.

SIR,—In the course of some recent experiments on organic bodies, I found

that carbazotic acid produced a copious precipitate when added to a solution of the sulphate of quinine: as the circumstance was new to me, I was induced to institute a series of experiments for the purpose of ascertaining the action of this acid on the principal vegetable bases.

The substances which I have submitted to experiment are—quinine, cinchonina, brucina, strychnina, morphina, narcotina, codeina, veratrina, solanina, conicina, emetina, and oxyacanthina.

The carbazotic acid and alkaloids were dissolved in alcohol (800), with the exception of narcotina, which was dissolved in æther.

The following table will show the action of the acid on the solutions of the above bases:—

Vegetable base.	Precipitate.	Soluble in	Insoluble in	Remarks.
Quinina.	Copious yellow.	Muriatic acid 1:130.	Sulphuric acid (1:5). Nitric acid 1:300. Acetic acid 1:050.	Crystallized with great difficulty. Colour unaltered by the action of nitric acid, but changed to yellowish brown by caustic ammonia and liquor potassæ.
Cinchonina	Ditto.		Sulphuric A. Nitric A. Muriatic A. Acetic A.	The precipitate is crystalline. Colour unaltered by ammonia and potash. When treated with sulph. and muriatic A. the colour is nearly removed.
Brucina.	Some shades darker.	Muriatic A. Nitric A. and moderately in Acetic A.	Sulphuric A.	When the precipitate is treated with hot alcohol, it assumes a dark orange colour, and is instantly converted into blood-red by the addition of a drop of nitric acid.
Strychnina	Colour intermediate between the preceding.	Muriatic A. Nitric A.	Sulphuric A. Acetic A.	The precipitate is exceedingly insoluble in acetic acid. When strychnine is dissolved in hot alcohol, the precipitate is not immediately seen, but appears in beautiful crystals as it cools. Colour unaltered by hot alcohol or nitric acid.
Codeina.	Yellow, but not copious.	Water.		
Morphina Narcotina Veratrina Solanina Conicina Emetina	None.			
Oxyacanthina.	Yellow and very copious.	Nitric acid.	Sulphuric A. Muriatic A. Acetic A.	The yellow colour is converted into brown by means of nitric acid.

From the above table we see that quina may be distinguished from brucina and strychnina by the insolubility of its precipitate in nitric acid; from cincho-

nina, by the alteration of colour on the addition of ammonia; and from *oxyacanthina*, by its precipitate undergoing no change of colour on the addition of nitric acid.

Strychnina and *brucina* may be easily distinguished by the greater solubility of the precipitate from the former in alcohol, and the facility with which it crystallizes. The most important circumstance, however, is, that when heated with alcohol, the precipitate of the latter becomes deep-orange coloured, and this, on the addition of a drop of nitric acid, is changed to a bright blood-red colour.

Both *brucina* and *strychnina* may be distinguished from *oxyacanthina*, the colour of the last being rendered brown by nitric acid.

With reference to the delicacy of this re-agent:—

One grain of the sulphate of quina was dissolved in 12,800 grains of water. A few drops of the aqueous solution of the acid produced a very perceptible precipitate.

One grain of *brucina* was dissolved in 3,000 grains of water: the aqueous solution of the re-agent indicated the presence of the base.

One grain of the sulphate of *strychnina* was dissolved in 6,000 grains of water, and, in this state of dilution, the effect of the re-agent was perfectly visible.

My attention is, at present, directed to the further investigation of the properties of carbazotic acid, and, if any practically useful results should ensue, I shall feel great pleasure in submitting them to your consideration.

I beg leave to subscribe myself, sir,

Yours very respectfully,

GEO. KEMP, M.B., Cantab.

Fellow of the Cambridge Philosophical Society.
Munich, March 25th, 1840.

ON THE
EFFECTS OF PARTURITION ON
THE NERVOUS SYSTEM OF
THE MOTHER.

By DR. CHURCHILL, Dublin.*

MR. PRESIDENT AND GENTLEMEN,—
Having been asked by your secretary, Dr. Brady, to fulfil a promise I made,

* Read before the Association of Physicians, April 6.

of introducing some cases for discussion, I offer you the following, which though not illustrative of any original observation, may, nevertheless, possess some interest.

And first, I would beg to call your attention to the effect of the process of parturition upon the nervous system. If, for example, you carefully examine a healthy woman previous to labour, and after delivery, it is impossible to overlook the great change which has taken place in her condition; even though her labour have been perfectly normal, of moderate duration, and with no accident subsequently.

The condition in which the woman is placed, cannot be considered as the consequence of the muscular exertion during labour, because it bears no proportion to it in amount and duration; and because the functions of other organs are more extensively deranged than we find them in cases of excessive exertion.

What then is this state? to what is it owing? in what does it consist?

It appears to me, to consist in a sudden and more or less severe *shock* to the nervous system, in consequence of the extraordinary disturbance to which parturition gives rise.

I have called it a *nervous shock*, because the phrase is already in use amongst surgeons, to describe a similar state occurring after an accident or operation. For instance, a workman in a factory has a limb torn off by the machinery, and he dies in two or three hours; but neither from hæmorrhage nor inflammation, for the former was prevented by the torsion performed upon the arteries, and there had not time enough elapsed for the latter. A post-mortem examination reveals no cause of death. Of what then did he die? Of the nervous shock.

The same explanation is given of the death which follows scalding or burning, provided it occur within a few hours.

Now this *nervous shock* is precisely what may be observed in certain cases of labour; especially after operations, and it may produce equally fatal results. It is not, however, confined to these cases, but exists more or less in all, and it requires but a little care to recognise it.

After ordinary labours, we find the sensibility of the brain generally diminished, though the organs of sense may be more sensitive than usual. The eye

has lost its brightness, and expresses only languor and exhaustion: it is, however, more intolerant of light as the ear is of sound, and if careful attention be not paid to these two points, cerebral excitement may result.

Again, the pulse indicates a degree of collapse, from the increased frequency to which it had attained during the second stage; it shortly falls as much or nearly so below the usual standard: at which point it remains until the patient recovers from the nervous shock.

The respiration generally preserves its relations with the frequency of the pulse, and may in accordance with it be rapid or slow and laboured. Various secretions dependent on nervous influence are changed in quantity and quality in consequence of the impression on the nervous system.

The patient recovers from the shock, under ordinary circumstances, after a few hours' repose and quiet, though the indirect effects are rather more permanent: and the progress of the convalescence is generally in proportion to the rapidity and completeness of this restoration.

So much for the nervous shock in its mildest form and under favourable circumstances. Now let us examine the condition of the patient, after a prolonged second stage, or after an operation; say that of version, in which the nervous shock is of an aggravated character.

The functions of the brain are much below par—the patient is depressed, though not anxious, with a degree of exhaustion as though she had been stunned. She lies on the bed without altering her position, with her eyes closed, or at least without observation; betrays no interest about her child, perhaps none about herself. The muscles are flaccid, and she can scarcely make an effort to move her limbs: her pulse is low and laboured, or quick and fluttering, and much weaker than usual: the respiration is either slow and oppressed, or hurried and panting; and the relation between the circulation and respiration is frequently broken.

In this state she may remain a considerable time, and then only by very slow degrees rally; or if the amount of shock be too great for the system, she will gradually sink, the collapse will deepen, and she will die. If a post-mortem examination be made, nothing is discerned to account for her death.

As far as we can judge, she dies of the shock or impression made upon the nervous system primarily, and, through that, upon the whole organism.

I shall now very shortly detail some cases which I have noted, illustrative of these remarks.

A few weeks ago, I was called upon to attend Mrs. K——, in her first confinement. She was one of twins, and was of a delicate constitution and highly nervous temperament. She was taken with labour-pains about 9 A.M., which recurred slowly until 12, when I visited her. I found the os uteri undilated, though not rigid, and the bag of the waters beginning to form. As the pains were rather feeble and distant, I left her for a short time, with directions to be sent for as soon as the progress of the labour quickened. In half an hour I was summoned in great haste, and on my arrival I found the child was born. The pains had suddenly increased in strength soon after I left, and three pains sufficed to expel the uterine contents.

There was but the usual amount of discharge, and subsequently some clots were expelled. She suffered a good deal from after-pains: but her condition for some time after the labour occasioned me much uneasiness. She seemed to be in a state of complete collapse; she scarcely spoke, and then only in a whisper, but lay in a state of utter exhaustion. Her senses were morbidly sensitive; the pulse was 140, small, and weak; the respiration was feebly and languidly performed; and it seemed doubtful for some hours whether she would not sink.

I requested a consultation, and my friend, Dr. Darley, was called in: he agreed with me that the case resembled exactly those where a severe nervous shock had been received; for excepting the after-pains, she had no local symptoms whatever.

We ordered opiates (which, however, she could not bear), cordials, and gentle stimulants, &c. By degrees the system rallied, but it was long before she recovered. Her pulse remained about 115, but I found that her twin sister's pulse (in health and in a state of quiet) was 120; which, of course, relieved my anxiety on this score.

The most remarkable circumstance connected with this case, is, that so severe a shock was produced by so short

a labour; the time which elapsed from my ascertaining that dilatation of the os uteri had scarcely commenced, until the birth of the child, not exceeding half an hour.

Similar depression is often seen after operations, and must be familiar to every accoucheur; from which some patients recover, and others die.

But the patient may die from this cause, even though the labour be terminated by the natural efforts; as the following case will prove:—

A patient in labour was admitted into the Western Lying-in Hospital, the year before last. The pains were tolerably strong, but the passages offered a good deal of resistance. Her condition continued favourable for about thirty hours, but then the pulse became more frequent, her skin hot, with a degree of restlessness; and a consultation was held. As a certain, though slow, progress was made, and as the suffering was not great, and, above all, as the patient expressed the utmost horror of instruments, it was determined to wait for two or three hours; and when I mention that it was by the advice of Dr. Darley that the delay was adopted, I offer the best defence of the line of practice pursued.

In two hours the head was pressing through the vaginal orifice; in three, the child was born alive.

During the last hour or two, however, the patient had suffered severely, and the expulsion of the child left her in a state of utter prostration. The nervous system seemed stunned; her countenance was expressive of complete exhaustion; the eyes were dull and heavy; the sensibility of both ears and eyes was diminished; the pulse was quick, weak, and fluttering; respiration rapid and panting, with deep sighing; the muscles were flaccid, and it required a great effort to move her limbs. Appropriate remedies were applied, but from this collapsed state she never rallied. There were no convulsive movements, and her intellect was clear until she died, which was in eight or ten hours.

We examined the abdominal and pelvic viscera, but they were perfectly healthy, and not a trace of any injury could be discovered. As far as I am capable of deciding, I should say that this patient died of the *nervous shock*. No one could doubt that she had suffered from this cause; and, from the condition

into which she was thrown, she never rallied.

About four years ago, I was called (as physician to the Wellesley Dispensary) to see a poor woman, in Hollis' Court, who had been some time in labour, but who had not sent for assistance until an hour or two before I saw her. I found her suffering from a quick pulse, and some degree of fever. The head of the fœtus was in the pelvis, and there was plenty of space, but the pains made scarcely any impression upon the child. Upon consultation with Dr. Darley, it was deemed advisable to use the forceps. They were easily applied, and the patient was delivered of a still-born child without much difficulty. After the expulsion of the placenta, she appeared very much exhausted, and very weak; without headache, and possessing her reason: the pulse was very slow and weak, and the respiration hurried and panting. The usual restoratives were ordered, and she seemed rather better. On paying a second visit in the evening, I learned that she had remained in the state I left her until six p.m., (the operation was performed at mid-day,) when she got weaker, and died rather suddenly. We obtained permission to examine the body, but discovered nothing to account for death; the abdominal and pelvic organs were perfectly healthy, and had suffered no injury.

Recollecting the depressed state in which we had left her, and carefully investigating her subsequent symptoms, we came to the conclusion that her death was owing to the *nervous shock*.

During the time that I was attached to the Wellesley Dispensary, we were summoned to a case at Ball's Bridge, which had been under the care of a midwife, and had been mismanaged. We found her with a quick pulse, hot skin, dry furred tongue, &c.; in short, with the usual symptoms which occur in a very prolonged second stage, with retention of urine in addition. From the latter she was immediately relieved; and no doubt could be entertained of the propriety of immediate delivery by the quickest means. I perforated the head of the child, but, from its putrid condition, found it difficult to extract it; I, therefore, introduced my hand for the purpose of turning, and brought down a foot; but, to our surprise, it was the foot of another child. I extracted it with tolerable ease; but it took a considerable

time to bring away the putrid one. The placenta was extracted.

During the first part of the operation the patient was delirious, but became quieter before it was finished. Afterwards she was exhausted and stunned; her breath laboured, sighing frequent, pulse rapid, small, and feeble, &c., &c.

I saw her in two or three hours after the operation; she had not rallied, though she appeared somewhat relieved. Her intellect was entire; no convulsions had occurred, the pulse continued frequent and weak, and the respiration was sometimes hurried; at other times slow. There was no pain on pressing the abdomen, and no complaint of more soreness of the outlet than usual. I called the next morning, but found that she had died during the night, without any new symptom; she gradually sank, and, at last, ceased to breathe.

We could not obtain permission to open the body, and, therefore, this evidence is wanting: but, from the symptoms, I do not myself doubt that the cause of death was the great shock necessarily arising from so tedious an operation under unfavourable circumstances.

I could easily accumulate cases; but I think these will suffice, and I shall, therefore, conclude by drawing your attention to one or two circumstances noted in some of these cases, and to the treatment which I have found most successful.

The patients most obnoxious to this effect of labour are delicate nervous women; those who have been allowed to continue too long in labour, or those with whom an operation is necessary; and the more severe the operation the more marked the symptoms, although I have seen them very striking after the mere extraction of the placenta.

It will have been remarked that in all the fatal cases the patient made no effort to rally from the state of collapse; and this I have invariably observed in such cases. When a rally is made, all danger from the nervous shock is over.

Another circumstance distinguishing all these cases is the total absence of any approach to convulsions, and the continued possession of the intellectual faculties until death: this is a very valuable guide in our diagnosis.

In the treatment of these cases, the first object is, of course, to recover the patient from the collapse; but the most

direct means are not the best. Vinous or spirituous stimulants are useful, but not the most useful remedies. I have always found opium the best means I could use; and I generally give it in the form of tincture, and in combination with ammonia. Ten drops of laudanum may be given every half hour, at first; then every hour, and, subsequently, less frequently. It appears to quiet the general disturbance, to diminish the shock to the brain, and to give the system time and opportunity to rally. At the same time a moderate portion of wine or spirits and water should be given at intervals sufficient to assist the effort to rally, but not so much as to cause violent reaction, and the patient be kept in perfect quiet, so as to encourage sleep. If this should take place, she will probably awake much refreshed, with a quieter pulse and equable respiration. If, on the contrary, the collapse should continue, our endeavours must be increased as the danger is more threatening.

When the imminent danger is past, great care will be still requisite, and all mental and sensorial stimuli must be carefully regulated rather according to the part, than the then present state of the brain.

The remainder of the cases I have selected I shall, with your permission, postpone to another opportunity.

Dublin, 136, Stephen's Green West.

FURTHER REMARKS
ON THE
RENEWAL OF THE VACCINE
VIRUS.

To the Editor of the Medical Gazette.

SIR,

As my friend Mr. Estlin pays me the compliment of saying that he always peruses my papers on vaccination with much interest, and as I can most sincerely assert the same of his, as coming from one whose exertions have been highly important to the cause we have both at heart, I wish to make some observations on the subject of his last letter, inserted in your journal for March 13th last.

Mr. E. endeavours to prove that the Vaccine Board, in their last report, are not justified in the assertion that the virus which they are now using is "the

produce of the original virus furnished by Dr. Jenner, which has now happily passed through successive generations of subjects in the course of forty-three years, and which forms the principal part of our supply."

As I doubt not that they can make their case good, I shall forbear any observations on this point, as not coming within my department; but it is especially the following passage of Mr. E.'s letter that I wish to notice. He says, "if he," (Mr. Aikin,) "or any of his colleagues, could verify, as the result of their own examination, that a stock of cow-pox matter is now in use, the original of which can be traced back for forty-three years, I am sure the profession will feel under much obligation for the establishment of a fact so valuable to medical science."

I know not what degree of presumptive evidence will satisfy Mr. E. in this particular; certainly it is not necessary to trace the genealogy of each transmission with the same accuracy that would be demanded of a claimant to a dormant peerage. Even were no register kept of the source of each inoculation, the very fact that there has existed for a long series of years a well-frequented vaccine station, in the same local situation, carefully attended to by the same individuals who had never been known to require any but their own supply for themselves and others, would of itself form a presumptive evidence of unbroken transmission in the same channel, sufficient for all purposes of fair physiological inference.

But as Mr. E. not unreasonably appeals to specified facts, and as I *am* in the habit of noting down the source of my own inoculations to be confined to my own stock, this will, I trust, be my excuse for stating my personal experience.

On turning back my register books year after year, I find an uniform succession of inoculation from my own patients without any foreign supply, up to January, 1821, being a period of full nineteen years from the present time. This being mid-winter, when, at all times, the applicants are very few, and of those few not many will bring their children out a second time, I find I was obliged to apply to my friend and former colleague the late Mr. Addington, whose station being at a Sunday-school room in the middle of Spitalfields, had always a much fuller attendance than

my own, and whose extreme, I may say punctilious, accuracy in registration of every thing connected with the subject, was well known to all his friends. I will now begin at the other and earliest end of my series. The Jennerian Society was established in 1803, and the stations in different parts of London were fixed, and the attending surgeons (gratuitously) were appointed in the course of the year. I do not know what is become of the registers of the Society; but, being a member of the first medical committee, I have a strong impression, almost amounting to certainty, that application was made to Dr. Jenner to furnish the first supply of virus, which was the more insisted on, as some early experiments on vaccination, made by Dr. Woodville, rather unfortunately, within the Small-pox Hospital, had produced a disease, often accompanied with pustules, which had for a time obscured the subject. Mr. Addington and myself took charge of a station in Bishopsgate-street; and, I presume, we derived our first supply of virus from the same (that is, Dr. Jenner's) stock. We continued together, in most amicable fellowship, till the institution of the National Vaccine Establishment, in March, 1805, when, being myself appointed one of the surgeons, I removed my station to another part of the same city ward to a room which I have occupied ever since. I know that it was a particular point with Mr. Addington to watch the comparative effects of vaccination year after year; and chiefly on this account he was at the pains, for a long time, to apply Bryce's test to nearly all his patients. In applying, therefore, in 1821, to this source to renew my broken chain of transmission, I was, in fact, only returning to my own source in early times, which I knew I could depend upon. Though it would be absurd in me to assert that it had never been changed or renewed from the cow, I can only say that I have never heard of any such change, nor ever myself had an opportunity of using virus taken directly from the animal, which, I think, I should have done had it been within my reach. I must beg to observe that I have never claimed an uniform transmission of my own stock of virus for so long a period as forty-three years; but I do claim the term of nineteen years from personal observation; and I think I have given strong presumptive evi-

dence that the chain was unbroken for about eighteen years more up to the first link which was furnished by Dr. Jenner himself. I must also add that I am only one out of several who have been running the same course, and whose experience might, perhaps, include a longer unbroken period.

Being one of the surgeons who returned to the establishment an opinion of the hitherto unaltered appearance of the effect following ordinary vaccine inoculation, I thought it right to state my reasons for this opinion, which I have done fully in a paper which you were so kind as to insert in your journal, May 18th, 1839. I will not intrude upon your pages by repeating them. They have elicited no further remarks from Mr. Estlin, so that I am unable to say whether they meet with his concurrence.

In the same paper I also made some remarks in defence of the Vaccine Board (quite as a volunteer I assure him), in their declining to adopt his renovated virus, and circulating it simultaneously with their own; and I also could not help expressing my opinion that it was quite unworthy of Mr. E. to extract an accusation of general want of trustworthiness in the Board, or, still worse, of deliberate intention to mislead, from a mere verbal over-sight in one of their reports, by which the word *million* is substituted for *thousand*, whereby an antiquity is given to their vaccination of *twenty thousand years*, a period when doubtless there were no cows to graze—no milkers to become diseased, and when the Berkeley Hundred of Gloucester was, perhaps, only tenanted by flying dragons and amphibious saurians. As Mr. E. has not scrupled to repeat this absurd accusation, I cannot do better than refer him to his own words in his very next sentence: “I do not make these remarks from any captious disposition to detect trifling inaccuracies in the National Vaccine Establishment.”

But to proceed to more agreeable matter. Wishing to make trial of Mr. E.'s renovated virus, I applied to him for some last June. In his letter accompanying the charged points which he sent me, he says, “Five months ago I should have cautioned you against making more than one incision in each arm; now the virus is so much less active that such advice seems unnecessary. The matter I now send is the

39th remove from the cow.” It appears, then, that it took some time, and several transmissions, before the virus was softened down, if we may so speak, to that mild and safe condition in which we uniformly find that which we have been so long using; and this gives countenance to the reports which we heard of the occasional production of severe and even alarming erysipelatous inflammation following some of the earliest trials of the renovated virus.

With the matter procured from Mr. E., I vaccinated four patients, and from these sixteen more—twenty in all; but of these only thirteen attended again. The results were as follows:—

The first failed entirely. On repeating the inoculation some weeks after, with other matter, vesicles were produced, but imperfect, dying away too soon, and the case was registered as unsatisfactory.

The second, a fine clear-skinned child, was seen again on the eighth day, when there were seven vesicles of as perfect and genuine cow-pox as I have ever seen, being of a pearly clearness, full of limpid fluid, and just hardened and reddened at the base by the incipient areola. Two days afterwards the areola was complete, regular in form, and not excessive, and the vesicles beginning to dry. In short, if I had wished to have the disease represented by an artist, I could not have selected a better subject.

I need not enumerate the other cases particularly. In all, the vaccination was quite correct, with some variation in the progress of the areola. In one, the vesicles were pale, hard, and flat, on the eighth day, but crept on successfully to full maturation. The last patient was not brought again till the seventeenth day, having gone through measles in the interval. There were four regular crusts in each arm, quite dried up, and contiguous to one was a pretty large ulcer, but shallow, and looking clean and healthy.

I then put an end to the experiments, and suffered this source of virus to die out. If Mr. E. asks why I did so, instead of adopting it in preference to my own, my answer is, that, whilst carrying on these trials, I took care to have other patients from my own stock running exactly the same course at the same time. I can truly say that, having the child with one vaccine source on my

right hand, and that with the other source on my left, I was utterly unable to detect any other difference in the appearance of each than what might arise from a little advance or delay of the areola. One sort might be called quite correct, and the other perfectly unexceptionable.

I consider, therefore, that we may now apply to Mr. E.'s renovated virus the same observations which Dr. Jenner makes concerning his own, in 1800. His words are these: "Whether the nature of the virus will undergo any change from being further removed from its original source in passing successively from one person to another, time alone can determine. That which I am now employing has been in use nearly eight months, and not the least change is perceptible in its mode of action either locally or constitutionally. There is, therefore, every reason to expect that its effect will remain unaltered, and that we shall not be under the necessity of seeking fresh supplies from the cow."—*Continuation of Facts, &c. 1800.*

In my opinion, the experience of many years only confirms this conjecture of the illustrious discoverer of vaccination. Though we have been obliged to abate part of our confidence entertained in the early days of this practice—of the absolute permanency of the security which it professed to offer, we have not yet obtained a shadow of proof, or even of presumption, that the renovated virus, however correct, promises more security to the coming generation than the original one, when selected with due care, has afforded to the now adult subjects of the earlier vaccination.

In fact, how can we reason on the subject of protection but from mere experience; when the acutest physiologist has never, that I am aware of, been able to throw the smallest light on that mysterious change wrought in the constitution by which a single attack of small-pox, in the mildest form in childhood, protects by far the greater number of persons from its most virulent contagion during a long life. View the bystanders round the bed of one whose features, swollen out of human shape, closed eyes, face covered with a black fetid mark, and throat choked with foul sordes, mask the extremity of this dreadful disease. One shall be a female, whose aged countenance still

bears the smoothness of youth. Ask her how she moves unharmed in this atmosphere of dense contagion; she will strip her sleeve, and, after some search, you will find a shallow irregular scar, the only remains of inoculation in early childhood, which, as she has been told by her mother, after two or three days of slight illness, was followed by the coming out of some ten to twenty pustules, after which all sickness disappeared, and they dried away in a week's time. Another by-stander shall be one whose manly features, mottled and smeared with deep scars and pitings, show how hardly, and with what a severe struggle for life, he has earned his protection. And yet, inferring from the rare but undoubted cases, where all protection has failed, we know that the second attack of small-pox will as readily visit the subject of the severe as of the mild disease.

Analogy, therefore, as far as it can be depended on, seems to show that there is a certain point at which the vaccine disorder gives its average security, and that every degree of local effect beyond this, whether shewn by wide-spreading erysipelatous inflammation, enlarged glands, and general irritative fever, is, at best, superfluous, and ought to be avoided if possible. This security-point, I have no doubt, is the conversion of the local into the constitutional disorder by, and during, the formation of the areola, which begins by hardness and tightness at the base of the vesicle, and is followed by its extension to the well-known ring of inflammation completed at a period varying from the eighth to the tenth day, or, sometimes, from interfering causes, protracted much later. In a paper of mine, on the interference of small-pox and other disorders with the progress of vaccination (*MED. GAZETTE*, Feb. 15th, 1834.) I gave several instances in which the vesicles proceeded to enlarge and fill regularly for several days, but remained quite pale, and felt loose and flabby under the skin, marking the interference of small-pox, of which the patient sickened directly after. Impending measles will produce the same effect. The vesicle will remain pale at the base, and quite loose in the skin; that is to say, will continue to be a merely local affection, whilst the measles proceeds through its regular course;

after which the vaccine areola will make its retarded, but accustomed, appearance, and the whole will terminate regularly.

I shall conclude by taking the liberty of recommending to vaccinators to have recourse, from time to time, to Bryce's valuable test, and re-inoculate on the fourth or fifth day after the first insertion. In this case the second vesicles will have their progress hastened, and they will assume the areola at the same time with the first. This undeniable proof of constitutional affection remains in full force in the vaccine virus of our old stock: I have even produced it when the second insertion was delayed till the eighth day; but were it to lose this power, I should think it right immediately to change the stock, and adopt either Mr. Estlin's or any other equally unexceptionable.—I remain, sir,

Your obedient servant,

CHARLES R. AIKIN.

7, Bloomsbury Square,
April 6th, 1840.

P.S.—At Mr. Estlin's request I sent him some points last June, charged with my old stock of virus taken on the eighth day, which, in fact, is the only period at which I ever use it—I presume, that he might compare its effects with his own. As I am curious to know whether the same similarity between the two occurs at Bristol as at London, I beg to invite him to make the communication.

VACCINATION EXTENSION BILL.

To the Editor of the Medical Gazette.

SIR,

THE bill for extending the practice of vaccination, now in progress through parliament, has been a sufficient time before your readers to enable them to form some opinion of its nature and probable effects.

I must confess my astonishment that it has not already called forth a loud and general expression of disapprobation; and I trust that you will, by inserting this communication, afford me an opportunity of directing the attention of the profession to the obnoxious features of the proposed enactment.

It will be recollected that this bill was introduced into the House of Lords shortly after, and in consequence of, the presentation of a petition from the Pro-

vincial Medical and Surgical Association, which, after shewing the present defective provision for vaccination, and the necessity for a more universal and better regulated system, suggests the remedy in the following terms:—

“That it appears to your petitioners to be the duty of the state to remedy this great evil by appointing regularly educated vaccinators, with suitable salaries, in districts sufficiently numerous to embrace the whole of the poor population of the country, and who shall offer gratuitous vaccination, at stated periods, to all within their bounds; keeping accurate registers of their proceedings, and communicating regularly with the National Vaccine Establishment.”

In attempting, however, to promote the object of the petitioners, the legislature proposes to substitute a totally different machinery, and to entrust to poor-law guardians and commissioners the entire power of appointing public vaccinators, of determining their salaries, of regulating their proceedings, and of inspecting their reports!!

Such a method of encouraging (?) vaccination (I hardly need say) was not originally contemplated by the Provincial Association; and the whole tenor of the Report of the Vaccination Section is adverse to the administration of the poor-law in this particular.

The following appear to be serious objections to the bill:—

1. Since the majority of general practitioners at present administer vaccination to the poor (either in a public, parochial, or private capacity), it is not expedient to withdraw from this numerous body the inducement to continue their services, nor *just* to set aside their claims on legislative considerations, by limiting to Union medical officers (a class comparatively few in number, and widely scattered in location) the facilities and advantages which the measure is intended to provide for a regular and efficient system of vaccinating the entire poor population of the country.

2. For not only paupers, but all persons who apply, may (according to this bill) be vaccinated by the Union medical officers. It is, therefore, calculated seriously to injure the interests of the general practitioner, partly by withdrawing from him some patients who are in the habit of paying him for vaccination, but principally by depriving him of opportunities of gratuitous

vaccination ; which he must be anxious to retain, not merely for the ends of science, but as a means of procuring supplies of lymph, under his own inspection, for his wealthier patients.

3. By entrusting public vaccination solely to the poor-law medical officers, the enactment is calculated, in some localities, to increase the prejudices against, or indifference to, this invaluable protection, which are still too prevalent among the lower orders.

4. Is it reasonable to suppose that the Poor-Law Commissioners and Board of Guardians are properly qualified to superintend the practice of vaccination ; to frame regulations for its performance and registration, and to provide a due supply of genuine lymph ?

The National Vaccine Establishment might, indeed, undertake these duties, but such an addition to the *medical* business of the Commissioners would be positively ludicrous, were not the evident inclination of government to entrust all matters affecting the lives and health of the community to the discretion of a Malthusian board, a cause of painful apprehension to every humane and reflecting mind.

But, 5thly, the most practical objection to the bill is, that it will extend the power already possessed by the poor-law authorities, of *contracting* for the performance of medical duties. After all that has been urged by the profession, and admitted by the Poor-Law Commissioners, against contract, it is marvellous to see so vicious a principle introduced as the main feature of this enactment.

Let the Commissioners speak for themselves:—

“ It is evident that their (the medical officers) tenure, as paid officers, is likely to be more permanent than an engagement under a contract annually renewable, and revisable, at the will of the Guardians ; and this prospect of permanence confers more importance and respectability on the office, and thus has a tendency to secure the services of a better class of officers.”—(See their Report, just presented to Parliament.)

This indirect and unwilling testimony to the inherent evils of medical contracts should decide the question.

But further: Contract frequently involves appointment by “ tender,” especially if, as in the contingency actually anticipated by the proposed Vaccination

Bill, the contract be not taken by the Union medical officer. We shall then, doubtless, see the office of public vaccinator put up by the guardians (as is still done in the medical appointments) to an unprofessional and discreditable competition, the real object being to reduce the customary remuneration.

6. Viewed in this light, the measure is directly at variance with the efforts which the Poor-Law Committee of the Provincial Association have long been making, for the better administration of medical relief under the poor-law ; each of their principal requisitions is set at nought by this enactment — namely, professional supervision, a reduction in the size of medical districts, and a fair scale of remuneration fixed by parliament.

The Provincial Association could not, therefore, consistently support the bill in the present form ; and I have the gratification of stating that the Secretaries of the Association have forwarded, within the last week, a memorial on the subject to the Home Office (and a copy to Sir James Graham, who conducts this Bill through the House of Commons), from which I have taken the liberty of borrowing largely in the preceding observations.

They suggest the introduction of a clause, *directing the payment of a specific sum for each person vaccinated* under the provisions of the act, and state their belief (founded on the representations of several Union medical officers,) that two shillings and sixpence per case would afford the lowest reasonable remuneration for careful vaccination, and for correct registration of the cases and their results.

Although this amendment would not obviate *every* objection that may be raised against the bill, yet it would have the effect of restricting the Union medical officers to *pauper* vaccination, and would thus protect the interests of the general practitioner, who may not be in parochial practice: also, by fixing a proper remuneration for each case, it would encourage a zealous and attentive performance of duty ; and would afford a valuable precedent for legislation on the general question of Poor-law Medical Relief.

Hoping that the course which the Provincial Association has taken, may be pursued, ere it is too late, by those bodies who are in duty bound to protect

the profession—I mean the Colleges and Hall—I am, sir,

Your obedient servant,
H. W. RUMSEY.

Gloucester,
April 18th, 1840.

ON THE
INCREASE OF MORTALITY
AT THE
DECENNIAL PERIODS.

To the Editor of the Medical Gazette.
SIR,

CONSIDERABLE attention having been called to the apparently curious fact of the great increase of mortality at the various decennial periods, I forward you the following table, compiled from the register of births and deaths, as it furnishes almost convincing proof that this irregularity in the ratio of mortality is to be sought for in the explanation that has already been brought forward, viz., that the greater number of those cases in which the age of the deceased is undetermined, are put down under the decennial periods. This table, drawn up from the returns from districts, in some of which the population was mostly agricultural, in others principally manufacturing, shows that the most considerable departure from the regular ratio occurs in those districts containing the greatest proportion of manufacturing population, whilst in those districts chiefly peopled by agriculturists, the mortality at the decennial periods but little exceeds that in other years. This was what might have been expected; for it is evident that, in a population such as that which peoples our manufacturing districts, constantly subject to changes of abode by the vicissitudes of trade, that the number of persons dying at a distance from their friends, surrounded only by casual acquaintances, who are not likely to be acquainted with their age, must be much greater than in an agricultural population, of whom the greater number are born and die on the same spot.

In compiling the following table, I have only taken the number of deaths occurring at the ages of 30, 40, 50, and 60, and compared them with those occurring at the ages of 29 31, 39 41, &c. The first column gives the ratio between the agricultural and manufacturing population; and the second the ratio of the mortality at the decennial

periods, 30, 40, 50, and 60, as compared with that at 29 31, 39 41, &c. Thus, when the proportion of the agricultural families inhabiting a district was to the manufacturing as 1 is to 0.53, the agricultural population being taken as the unit, the deaths at the decennial periods only exceeded those on the preceding and subsequent years in the proportion of 1.246 : 1; but when there is a preponderating majority of the manufacturing population, we find, as in the last line in the table, that the deaths at the decennial periods exceed those in the adjoining years in the proportion of 2.013 to 1.—Your obedient servant,

JAMES BLAKE.

University College,
April 10, 1840.

Proportion of agricultural population to manufacturing.

1 : 0.53	1.246 : 1
1 : 0.64	1.293 : 1
1 : 0.95	1.552 : 1
1 : 3.7	1.357 : 1
1 : 5.5	1.326 : 1
1 : 45.7	1.798 : 1
1 : 68.9	2.013 : 1

Proportion of deaths occurring at the decennial periods above alluded to, as compared to those in adjoining years.

MEDICAL GAZETTE.

Friday, April 24, 1840.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

THE REPORTS OF THE CHARITY COMMISSIONERS.

HAVING concluded the publication of the abstracts of such of the Reports of the Charity Commissioners as we thought likely to be acceptable to our readers, we may be allowed to offer some few observations on those portions which are of more peculiar interest, and which, in the effort that was necessary to compress materials, already ponderous and very dense, into less than one-fiftieth of their original volume, may have lost some of that degree of prominence which their importance deserves.

Among the confirmations which the

Commissioners' Reports present of several principles which we have often taken opportunity to support, we would point to the fact of nearly £90,000 a-year being possessed by three hospitals, from the accumulated funds of voluntary benefactors, as a proof of the willingness of the public to give more from motives of liberality than they will yield upon compulsion, even to objects whose necessities are equal.

With reference, also, to the propriety of placing the power of distributing the funds in the hands of those who have themselves contributed largely to them, rather than in those of disinterested persons appointed by the legislature, or by any other body, the reports furnish important evidence. They prove, that it is absolutely necessary to hold out the privilege of management, as an inducement, among other motives, to the wealthy to become contributors to hospital funds. Thus, the long-continued dispute which terminated in the virtual removal of the corporation of London from any considerable share in the management of the hospitals of royal foundation, originated in the demands of successive benefactors, that, in return for their donations, they should be admitted to a share in the distribution of the general funds; and while, in a series of years, vast sums have thus been accumulated from the gifts of those to whom no other return was made than an admission to this privilege of management, one cannot doubt, that had this right not been granted, a large portion of these donations would have been withheld. Indeed, this is proved by the contrast which the funds of Guy's hospital present to those of the other two. There, a limited number of governors is appointed, who are not required to be benefactors, and no amount of donation is deemed to constitute any right to the office of governor. The result has been, that, with one exception, no im-

portant sum of money has ever been given to the hospital since its foundation; but that one exception was a munificent bequest of nearly £200,000, by a gentleman who, during his life, had taken an active part in the management of the establishment, and had had the gratification of planning many of the buildings, &c. of which he intended that his own money should defray the expenses. It is no imputation on the benevolence of Mr. Hunt to say, that had Guy's Hospital been managed by a board of Government Commissioners, or any other similarly-constituted public body, his wealth would have flowed in some other direction, over which he could himself have exercised peculiar control.

It is singular that, with many facts of this kind before them, there should still not unfrequently occur indications of a feeling, on the part of the reporters, that it would be better if the management of hospital charities were placed in the hands of appointed boards or paid commissioners. The only thing that could, in our opinion, warrant such a change, would be a proof that the funds of these institutions are already large enough, or too large, for the purposes they are intended to fulfil. In that case, no doubt, a few well-appointed managers, who would make their office their chief business, might conduct all the affairs of a large hospital as well, or perhaps better, than a large body of governors. But if it be deemed desirable that the funds of these institutions, large as they now are, should be still further increased (and we imagine that no one will be inclined to affirm the contrary,) assuredly no more effectual method could be adopted to prevent that desirable object than to exclude the benefactors from all power of disposing of their own donations. It seems to us that it would not be less mischievous than to annul the right which every one now possesses of

leaving his money for whatever purpose he pleases, and to order that all who wish to bequeath property for benevolent designs should leave it to a general fund, from which it should be distributed according to the taste or the judgment of a government-board of commissioners. The comparatively small number of bequests or donations that are made without the specification of some distinct purpose on which they are to be expended, affords sufficient proof that universal and impartial philanthropy is so rare a quality that it is necessary to permit and encourage each individual to give to his charitable aspirations any direction which is most in accordance with his own feelings. In the case before us it is quite clear that the number and amount of donations does now, and always will, bear a direct proportion to the degree in which the donor can order their expenditure; and that if pecuniary support is still required for the hospitals, it can only be obtained by offering in return a share in their management.

It would be absurd to say that this plan of government by benefactors is faultless: it has certainly not a few defects, although far fewer and less important than those which have been attributed to it. For example, upon the evidence of these reports there is not the slightest ground for the charges that have been urged, with as much clamour as absurdity, that governors, under the guise of charity, are, in fact, charitable only to themselves, using their influence to procure trade from the hospital for themselves or their connections. The attention of the Commissioners was directed particularly towards this point, and with no disinclination to the discovery of such practices, but in vain: not one instance could be detected in which a governor had used his privileges for his own pecuniary advantage. Neither do the few faults of the present system lie in the general management

of the funds, for which (at least in the City hospitals, to which only the reports relate,) the business-habits of the greater part of the governors peculiarly qualify them; but rather in those parts of the management which are strictly professional.

It cannot be denied that there is some justice in the remark of the commissioners, that there cannot be a security of competency in the medical staff of a hospital, when its members are selected by those who have not any more power of discriminating between the various degrees of professional capacity, than any other portion of the public. At the same time, amidst the various plans that exist either in theory or in practice in the present day, it would be difficult to find one which with so few faults combines so many advantages. The only tribunal that could have any superiority in respect of competency in judgment over that of the body of hospital-governors, would be a professional one; for as far as we have been able to observe, the appreciation of medical talent is not at all more accurate among those who are exalted in either rank or intellect, than among the average of the common-sense community. No government, for example, as far as we know, has ever shown more tact in the choice of candidates for situations requiring medical talent, than the governors of hospitals generally do; indeed, the former usually exhibits less, because their judgment is apt to be biassed by a greater number of circumstances. But suppose the system of professional tribunals were adopted; how instant would be the beginning, how distant the end, of the influence of professional partizanship and animosity! To judge fairly in such a case, men must be more or less than mortal who could dismiss from their minds all the prejudices of professional attachment or opposition which must in every case exist. Ample experience has shewn that, in the *concours*, there

is often no more security for the best candidate than there is in the system usually adopted in this country.

Neither must it be forgotten, that the unprofessional judges pay for their privilege, and by their payments furnish the circumstances for which the candidates are willing to submit themselves to judgment. The share in the election of medical officers is peculiarly that part in the privileges of the governors of each charity, which constitutes the strongest inducement to them to increase its funds; so that at the present time it is probable that a large proportion of the funds of several hospitals, and perhaps of all the dispensaries and smaller institutions in the metropolis, are derived from the connections of the medical officers, who thus, in their desire to serve their friends, confer a far greater boon upon the poor.

The system of concours before professional tribunals can be practicable, only when the hospital funds are drawn from public sources, and ultimately from general taxation; and if the funds for the charities were at all times sufficiently large and secure, it might not be a difficult task to invent a plan by which the most competent among the aspirants for places upon the medical staff, would be selected with at least as much certainty as the most accomplished candidate in a university examination. But in this country, this object, however desirable, can never be the only one to be kept in view; its attainment must always be prevented from clashing with the still more desirable object of augmenting the hospital funds; and the one must sometimes be sacrificed to the other. The power of appointing the medical staff is one of the greatest inducements to subscribers, and surely very urgent facts of error on the part of hospital governors — facts such as the reports present no example or hint of — should be ad-

duced, before this inducement to benefactions should be cut away. Let the Government interfere, and many of our charities would at once become bankrupt.

But, in fact, the evil of the presumed incompetency in the electors of medical officers, is practically much less than the statement of the possibilities of error would lead one to expect. The Commissioners judiciously point out, as a remedy for this as well as for many other faults, which thinkers who are not lookers-on might expect, the existence of the medical schools, which are now attached to all the hospitals of the metropolis, and of many of the larger provincial towns. The effect of a class of pupils, as they rightly observe, is to put each medical officer upon a constant trial of his skill, by judges who are not only in general competent for decision, but are universally anxious to exhibit their own learning by detecting the errors of those who undertake to be their teachers. Thus there is at the same time insured, a constant effort on the part of each to do the best he possibly can for his patients, so as to secure the reputation which is so valuable to him among the pupils; and each is tried, not by his skill in any task that might be assigned preparatory to his appointment, but in the very work which his office calls upon him to perform. Nor is this all the benefit that the hospitals derive in this respect from the schools; they serve as a kind of training-ground for the future staff, in which, by continued exercise either in lecturing or some other occupation, those stores of knowledge are obtained which no other circumstances could lead to: and in which, moreover, an opportunity is commonly afforded for judging, upon the evidence of a long-continued intercourse, of the fitness of the several candidates for the higher offices. But, in short, with numerous apparent sources of error, this English sys-

tem of election will very fairly stand that test which is by far the severest that can be applied to it, or to many other doubtful points—from the proof of a pudding upwards; and for the general excellence of its result, we would require no further evidence than a fair comparison of the abilities of the hospital medical officers in this and in any other country, either in the present day or in any past time.

PROBLEMS IN MEDICAL ETIQUETTE.

To the Editor of the Medical Gazette.

SIR,

I REQUEST to be permitted to occupy a small portion of your valuable space in proposing to your readers one or two problems on the important subject of medical etiquette. If the medical profession, as a body, are to maintain a good position in society, it can only be effected by the cultivation of mutual respect and forbearance amongst the members. In order to promote this end, it is indispensable to adopt a good system of ethics, in which the conduct of the practitioner shall be determined in every variety of contingency. The circumstances which have suggested these problems are the following, and are related in the third person, with a view of securing perfect impartiality:—

Mr. D. O. Edwards operated in a case of varus of both feet, on the 23d of January last. The patient, a boy about nine years old, after a month's careful treatment, perfectly recovered. A Mrs. Page, residing in the same neighbourhood, and who had a daughter with a deformed limb, saw the boy after his cure, and sent to request Mr. Edwards would call and see her daughter. He complied with the request, and found Miss Page, a young woman 23 years of age, affected with atrophy of the right leg and thigh, and simple talipes of the right foot. He explained to Mrs. Page the nature of the malady, and undertook to restore the limb by division of the tendo Achillis, and regulated muscular exercise, so far as to do away with the use of the heavy iron apparatus

which she then wore, and to render a thick cork sole to her shoe the only aid necessary. Mrs. Page agreed that Mr. Edwards should perform the operation, provided Sir James Anderson, who had previously attended her daughter for hysteria, should say that it would not injure her health.

Miss Page accordingly waited upon Sir James, and brought back a message from him to Mr. Edwards, requesting Mr. E. would call upon him, and "explain his views of the case." Mr. Edwards was then affected with rheumatic ophthalmia, and found it inconvenient to go out.

A few days afterwards, Miss Page called upon Mr. Edwards, stating that Sir James wished her to take the opinion of Dr. Little, and had given her a letter of introduction, and she had come to ask Mr. Edwards if he had any objection to her going. Mr. E. said he had not, and gave her his card, desiring her to tell Dr. Little what he had said as to the nature and proper treatment of her case.

Some days after this interview Mr. Edwards called upon Miss Page to fix the day of operation, when Mrs. Page placed in his hands a letter from Dr. Little to Sir James Anderson, in which, after giving the same view as had previously been given by Mr. Edwards, he volunteered to perform the operation gratis, and suggested that Miss Page should take lodgings in his neighbourhood for the purpose.

Mr. Edwards, having stated to all the parties the sense he entertained of their conduct, received communications in reply.

Miss Page writes thus: "When I saw Dr. Little, I only stated your opinion upon the subject, and gave your card; I did not state that you offered to do it yourself, as I supposed Sir James had mentioned it in his note, and that Dr. Little was referred to merely for his opinion. Dr. L. said he wished to see me again: with this wish I made Sir James acquainted, to which he (Sir James) replied that he supposed I had not informed Dr. Little that Mr. Edwards wished to do it. I said I had not, as I had expected he had mentioned it in his note. Sir James then said he should not know how Dr. Little understood it until he heard from him. It now appears Dr. Little has not had a right understanding," &c.

Sir James, in his note, states, "I am not aware Dr. Little has any desire to operate on Miss Page; nor am I aware she is your patient: she has been under my care for some years, and still is so. The only message I sent to you was to say, that if you called on me I would hear your views, and then give her my advice." Mr. Edwards infers from this statement that Sir James had not read the letter which Dr. Little had written to him some days before.

Dr. W. J. Little observes, "I believe I know my duty to a fellow practitioner too well to contemplate wresting a case from his care. I regarded the wording of Sir James's note as indicating a desire that I should undertake the case, the more particularly as Sir James stated the patient was 'very desirous of obtaining my opinion.' The patient did not inform me that you or any other surgeon had offered to operate, or had ever given an opinion of the curability of the case. She mentioned that Mr. Edwards, of Chelsea (whose card she left) had seen her foot, but nothing more; and the inference from Sir James's note was that she was under the care of no one but Sir James. Perhaps had I been able to spare her the time for a longer interview, she might have communicated to me the particulars of her visit to you, which she omitted to do."

Mr. Edwards being satisfied with Dr. Little's surrender of the case and explanation, wrote him a note exonerating him from blame, and in delicacy to Dr. Little, named Mr. Weight, of Wokingham, as the surgeon who should take the case for the future. Mr. Edwards' ill health prevented him for a week or two from taking any active measures. On the 9th April, however, he received the following communication from Dr. Little:—"Miss Page has again called on me requesting me to perform the operation, stating you have been mistaken in supposing she had consented that you should do it; I should be very happy to throw a case in Mr. Weight's way, but cannot in this instance, as in consideration of Miss Page being Sir James Anderson's patient, and of her urgent request, I have determined to divide the tendon (the smallest part of the treatment), and attend to the mechanical and other treatment myself."

Mr. Edwards did not think proper to comply with this unceremonious setting aside of his claims; but wrote on the in-

stant a note to Dr. Little, refusing his consent to the proposal.

Dr. Little having taken no notice of Mr. Edwards' note, that gentleman infers that Dr. Little has performed the operation.

The above detailed are the circumstances which Mr. Edwards submits to the judgment of his medical brethren. He is conscious that the injuries which he deems have been inflicted upon him, are, from his humble position, of little consequence in themselves to the profession; but as indications of the principles which are to regulate the intercourse of medical men generally, he cannot consider them as of little moment. He would submit the questions in the shape of the following problems:—

1.—Did the sending for Mr. Edwards by the parent of the patient, and the subsequent conditional consent that he should operate, constitute Miss Page *pro tempore* Mr. Edwards' patient?

2.—Did Sir James Anderson's previous attendance on Miss Page for hysteria, authorize him to interfere in the surgical question; to endeavour to remove Miss Page from Mr. Edwards' care; or in short to do more than answer the specific question that was proposed to him?

3.—Did the transmission of a request from Sir James to Mr. Edwards, that the latter should explain to Sir James "his views of the case," imply an admission on the part of Sir James that Mr. Edwards was for the time in surgical attendance on Miss Page?

4.—Was Sir James bound or not in his communication to say, that a surgeon was already in attendance?

5.—Was it impossible for Dr. Little to suppose that; and, therefore, unreasonable to inquire whether the surgeon, who had taken the trouble to examine the case, and to send him his card, had undertaken to treat the patient or not?

6.—Under the circumstances which have been detailed, was Dr. Little, or would any other surgeon in a similar predicament, be justified in resuming the management of the patient?

I have now exercised your permission, in placing my problems before the profession. I think their dispassionate consideration must lead to good, and point out the existence of certain maxims of professional behaviour, the judicious expression of which, in so many propositions, must confer an obligation upon

every rank of medical men. I know no one, sir, better suited than yourself to perform this delicate task.—I am, sir,

Your most obedient servant,
D. O. EDWARDS.

15, Cheyne Walk, Chelsea,
April 15, 1840.

ROYAL MEDICO-CHIRURGICAL SOCIETY.

PATHOLOGICAL DEPARTMENT.

April 21, 1840.

DR. CLENDINNING IN THE CHAIR.

Case of Medullary Tumors affecting the Diploe and Cancellated Structure, in numerous distinct Bones of the Skeleton.

MR. ARNOTT had, on the table of the Society, six different preparations and models, illustrating disease of the bones in a patient who was under his care. He first drew attention to a model representing a large tumor developed on the left side of the os frontis, and extending inwards upon the brain. He shewed also a model of a portion of the brain, which exhibited the surface situated under the tumor flattened and depressed; and he likewise pointed to the skull cap, in which the tumor had been formed. In reference to the disease in the skull, he began by stating that the patient, who was a man of 48 years of age, came to him in November 1836, requesting to have the matter evacuated from a swelling situated on his temple. He recognized the man to be a patient from whom, two and a half years before, he had removed the left arm at the shoulder-joint, for medullary tumor seated in the upper head of the humerus. The patient had perfectly recovered from the operation at the shoulder-joint, and continued from that time in good health. Mr. Arnott suspected that the swelling on the temple, for which the man presented himself again, was a tumor of a similar nature to that which had been seated in the humerus. It was soft and elastic to the touch, and had much the sensation of its containing pus: yet it had never given him any pain, nor had it throbbled. The patient merely wished to get rid of it for its inconvenience in wearing his hat. On further questioning him it was learned, that in the right arm, which was the opposite arm to the seat of the disease, he experienced a certain degree of weakness; for example, he could not freely turn the key in unlocking a door. With this exception, there was no other evidence of the brain being affected by the contiguity of the tumor. To pursue the history of the patient to his death:—He remained nearly

in the same condition, with little increase in the size of the swelling, for about two months. A tumor, apparently corresponding in its nature with that situated on the temple, was then observed on the sternum. He was seized, at this time, with influenza; of which complaint he died, no new symptoms referable to the brain having been manifested in the meantime.

Mr. Arnott observed, that on examining the skull, the tumor which presented on the temple was found to be contained in a space intervening between the pericranium on the one hand, and the dura mater on the other; both of these membranes being extended over the tumor, the one above and the other below. The brain was depressed by the internal lobe of the tumor to a considerable extent, as exhibited by the model on the table; but its structure was sound, as were also the pia-mater and arachnoid covering it. On cutting into the substance of the tumor, it was found that the bone, at the part where the tumor was situated upon it, was completely destroyed; so that after maceration, a large ragged hole was left. The substance of the tumor was soft, and of the colour of currant-jelly, although of firmer consistence. A rim of bone rising from the exterior margin of the hole through which the tumor projected, surrounded the base. Upon sawing through the skull, to expose the brain, it was found to be soft and easily cut with the saw; and on closely inspecting the structure of the bone, it was perceived that the diploe, in circular patches, or circumscribed parts here and there, contained portions of the same soft morbid matter which formed the composition of the tumor. This appearance was more clearly exhibited, when the skull cap was held between the eye and light of the window. After maceration, when the medullary substance that had occupied the diploe was removed by the process of putrefaction, the space between the tables presented the appearance of having been undermined—the tables themselves preserving very nearly their natural structure and relations, being only slightly absorbed by the pressure. It was especially remarked, that no spicula or other projections of bone, extended into the tumor, or grew from any part of the surfaces of the skull, either internally or externally. The disease, on the contrary, was limited in its seat to the diploe; and the morbid matter seemed only to affect the outer and inner plates of the skull, by the absorption which its gradual growth produced. To pursue the examination more minutely, the outer table of the skull was filed down over a considerable extent of the preparation, for the purpose of exposing the diploe and channels of the veins: but it cannot be said that any change of

importance in the structure, beyond what has been already described, was disclosed in this manner.

Mr. Arnott next proceeded to describe the morbid appearances in several of the other bones of the patient's body. He examined the clavicle, scapula, sternum, vertebrae, ribs, and femur; and in all these bones he found disease, analogous to what has been already described as existing in the skull: in all, it was remarkable that the diseased mass occupied the interior, cancellated structure of the bones, or had commenced in these parts; and only involved the cortical structure in an indirect or partial manner. Beautiful sections were presented, to show the tumor completely filling the central cavities and cancelli of the humerus and femur, being only bounded by the cortical layers of these bones. It was noticed, in reference to the sternum, that the two layers of which it is composed were parted from each other more than is natural, apparently by the effect of the tumor contained in the diploe, separating them as it increased in growth. The morbid structure varied in its colour and consistence to a certain extent, in the different bones. In the upper head of the femur, it was of a purple red colour, and presented many of the characters as to consistence and general appearance of the granulations in an open wound. Here Mr. Arnott thought the tumor was exhibited in the earliest stage of its formation: in the sternum, it was harder and firmer; and instead of being of the colour of black currant jelly, had a pale grey appearance, like brain long preserved in strong spirit; which appearances he thought indicated that the tumor had existed for a considerable period in this bone.

All the viscera of the body were examined with care, but in none of them was there any vestige of the same disease which was so extensively developed in the interior of the bones. The lungs alone were morbidly affected; they were gorged with the accumulated secretion of the bronchial tubes, and that to a degree sufficient to account for his having died from the attack of influenza with which he had been seized.

In remarking what were the most important deductions to be drawn from the above case, Mr. Arnott adverted, in the first place, to the extraordinary extent to which the disease was distributed over the bones in this patient. It can only be a matter of conjecture how far the disease had invaded the osseous system generally, when, two years and a half before the death of the patient, he had performed amputation, for disease of the same kind seated in the humerus. It is, however, an interesting fact to bear in mind that the patient survived the operation for that

length of time, and was carried off eventually by a different complaint—the influenza. In common cases of medullary tumor, involving the bones of the extremities, amputation is occasionally objected to, on the grounds that the disease will return in the stump, however early you may remove the limb. In this case, the stump remained perfectly unaffected and sound. It has been stated, by Cruveilhier, that when the malignant disease in question originates in the bones, we are more especially sure of finding traces of it in the different viscera. This remark does not at all accord with what was observed in the present case. The successful issue of the amputation may have been due to two particular causes; first, as the disease evinced a peculiar disposition to affect the bones more than any other tissues, we may understand how the integuments and muscles healed favourably, and the stump continued sound. Secondly, as the limb was removed at a joint, and there was, therefore, no sawing through of any of the bones, so as to expose the diploe, which was the especial seat of the disease, the danger of the disease re-appearing in the limb which was the subject of the operation, and causing an unhealthy stump, was much less than it would otherwise have been.

Adhesion of one of the Semi-lunar Valves of the Aorta to the surface of that vessel, and closure of the orifice of one of the Coronary Arteries.

Dr. Kingston exhibited to the society a portion of a heart and root of the aorta which he had removed, on Friday last, from a patient whom he examined in company with Mr. Walsh. On inspecting the preparation, two of the valves, at the orifice of the aorta, were seen, together with the orifice of the right coronary artery: but the third valve, at first view, seemed deficient, and no trace could be perceived of the orifice of the left coronary artery. By examining the parts more closely, it was observed that the valve which appeared deficient, and the part of the parietes of the aorta in relation with it, were incorporated into one substance, being united together by the intervention of atheromatous deposit. The amount of this deposit was not considerable: hence the valve, so far as its structure could be recognized as such, or be distinguished from the coats of the aorta, was not separated from them to more than a quarter of an inch. The opening of the left coronary artery was blocked up by the atheromatous deposit just described; and in such a manner that, in order to discover its situation, it was necessary to introduce a probe into the coronary artery, where it encircles the base of

the heart, and to direct the point towards the aorta. When this was done, the probe was found obstructed at the orifice; and it could only be exposed by cutting into the diseased part between the valve and inner coat of the aorta, and then the commencement of the coronary vessel, with the probe within it, was seen. The aorta was loaded, on its inner surface, with atheromatous deposit and calcareous conerctions. The left ventricle of the heart was dilated, and its walls comparatively thin. The lungs presented the appearances usually seen in cases of chronic bronchitis; and circumscribed clots of blood, termed apoplexy of the lungs, were found in several parts of their substance.

The patient, from whom the specimen above described was taken, was a female, fifty-three years of age. Some years before her death she had suffered from rheumatism, and had also dyspepsia. In addition to these complaints she was subject to violent dyspnœa. Occasionally, when walking, she would become suddenly faint, and fall; and this syncope was attended with paroxysms of difficult breathing. At night, she sometimes awakened out of her sleep with similar sensations, and had to sit erect in order to relieve the dyspnœa. These attacks became more frequent and severe subsequent to much distress of mind, brought on by her husband meeting with an accident, of which he soon died. In observing the sounds of the heart, over the semilunar valves, the first sound was only marked by a slight roughness; in the second, there was a decided, strong, blowing murmur. The pulse was generally found regular.

Case of Placental presentation.

Mr. Bainbridge brought, for the inspection of the Society, a uterus at the full period, in which the placenta adhered to the parts around the os uteri. The woman had been attended, shortly before death, by the assistant of a general practitioner in her neighbourhood, and Mr. Bainbridge was only called to make the post-mortem examination. He learned that the patient, three weeks before her death, and when near the period of her confinement, was seized with uterine hæmorrhage, just after straining to lift a heavy bucket of water. The hæmorrhage continued to a certain extent daily, until she died, exhausted by the loss of blood, not having been seen, in the meantime, by any medical man. The placenta, upon dissection, was found adhering, with unusual firmness, to the walls of the uterus, with which it was in contact. The principal part of the blood-vessels of the uterus were seen congregated towards this part. The os uteri was only dilated to an inconsiderable degree, and was peculiarly rigid and unyielding.

ROYAL INSTITUTION.

Friday, April 10th, 1840.

MR. NASMYTH delivered, at the Royal Institution, a very interesting lecture,—*“On the Functions of the Mouth, and the Structure of Recent and Fossil Teeth.”*

It comprehended a sketch of the process of assimilation, in the most extended sense of the term, as denoting that organic function by which anything whatever is converted into the nature or substance of another. The lecturer explained that it was to the exercise of this function that all vital changes were to be referred, and that, were it paralyzed, the tide of life, which now holds on in one steady, undeviating, unremitting course, from the lowest vegetable up to man, would instantly become stagnant. Nor is the organic world alone affected by its operation: the crust of the earth fulfils the office, as it were, of a general mouth and stomach to plants, from which their roots unceasingly derive nourishment; and the air contributes to animal assimilation by modifying the blood in the lungs, whilst, in plants, it acts in a similar manner on the juices in the leaves. Thus is every part of this globe pervaded, as it were, by the current of assimilation. With respect to the changes constantly taking place in the animal frame, Mr. Nasmyth strikingly remarked, that it is only after death has entirely removed the whole body from the sphere of vitality that any part of it assumes a character of permanency; but that then such is the indestructibility of some parts of that same animal structure, which, whilst living, had been undergoing incessant change, that they will be found to have endured through a lapse of countless ages, the extent of which the geologist alone can calculate, and to be altogether unaffected by the convulsions which, during that vast period, have rent the bosom of the earth in which they have been reposing. The lecturer then proceeded to describe the mouth as the original and essential constituent of the assimilative apparatus, which, he said, even in its most perfect form, may be regarded as merely a complicated extension of the buccal cavity, whilst, in its simplest form, it comprises nothing more than a rudiment of the latter. In the lowest classes of animals, however, it must be remembered, the different forms of the organization of the mouth are as peculiar to their respective species, as strictly adapted to the particular requisitions of the individual, and as typical of the whole system of the animal, as in the highest. The lecturer next gave a brief sketch of the organs of assimilation in their progress from their most elementary condition in

the zoophyte to their most perfect in the mammalia. Wanting time to particularize their especial modifications in each class, he selected the mouths and teeth of aquatic and amphibious animals for more prominent consideration, shewing how they were in beautiful harmony with their peculiar requisitions. The mouths of the dolphin, crocodile, shark, and lepisosteus, were exhibited as incomparable examples of machinery for seizing, holding, and dividing the bodies of their slippery prey. Indeed, the whole of this part of the discourse was illustrated by a great variety of valuable, curious, and appropriate preparations. The teeth of the crocodile and shark are so often broken and destroyed in their ferocious combats, that nature has provided them with many successive and complete sets of teeth, which may be brought into use as required. Other teeth, as those of the pike, become ankylosed, or fixed firmly and immovably to the jaw, so that they cannot be removed in even their most violent encounters. Specimens of both of these were exhibited. The lecturer then shewed, in an admirable manner, that activity and energy, in the character of an animal, were always accompanied by rapidity of assimilation and strength in the assimilative apparatus. This was exemplified by comparing the fish just mentioned with the whale—a toothless animal—which, floating at ease on the surface of the deep, sucks in diminutive, unresisting prey. With the same view, birds of prey were compared with the grass-eating goose—beasts of prey with herbivorous animals. The truth of these observations could be demonstrated even in the human species: a well-developed mouth, furnished with strong and powerful teeth, capable of perfectly performing the function of mastication, introduces the food into the stomach well prepared for complete digestion, and, of course, accelerates that process which thus duly nourishes the system, and obviates all redundancy and oppression: under such circumstances, the osseous system is also well knit, and the chest well developed—all in consequence of the activity induced by the due and complete performance of the function of digestion. The character of the animal, the lecturer ingeniously said, is often beautifully expressed by the mere apparatus of the jaw. Thus the powerful teeth in the front of the mouth of the horse, both above and below, indicate his celerity; whilst the more sluggish ox has comparatively weak teeth in the upper jaw, and none below. The maxillary apparatus of the herbivorous animals amongst the mammalia shews that they are destined to be the drudges of mankind. In man we observe none of the manifestations of

extreme activity on the one hand, or of sluggishness on the other, which characterize the different orders of lower animals; but in him the faculties which are distributed in various degrees to the other species are so concentrated as to produce the most complete harmony, and the most extensive range of action; in like manner his teeth are the most harmoniously developed and perfectly formed. The limits of a single discourse being altogether insufficient for tracing the various parts of the mouth in the progress of their development, the lecturer now selected the teeth for the exclusive consideration of his audience. All teeth, he said, may be regarded as cones or wedges, of which there may be one or more in each tooth more or less acute. The grinders of herbivora consist originally of several wedges or cones. The front teeth or incisors are generally wedge-shaped. The canines are generally simple cones; and the grinders of the carnivora present a combination of the latter. Sometimes the teeth are composed of a series of cones or wedges bound together at their bases, as in the grinders of the elephant, in the beautiful little incisors of the flying lemur, *sus æthiopiensis*, and others. The only exception to the cone or wedge-shape, in the construction of teeth, is presented by those of several fishes, such as the wolf-fish, the *myliobatis*, &c., which are in the form of pavements of various kinds, and which are for the purpose of breaking down the hard shells by which the bodies of their prey are covered and defended. The simplest form of perfect teeth is that in the human subject. It is a remarkable fact that no other conformation of mouth than that of man could admit at once of perfect articulation, and of a proper mastication of food. "The mouth," said Mr. Nasmyth, "may be considered to fulfil the most essential part in the animal and intellectual life of man; for it is not only in him, in common with other animals, the essential and original element of the apparatus of assimilation, but it is also the organ of intellectual expression, and as such is equally indispensable to the existence of the race; it is also the grand agent for the improvement of its condition, and for the communion of social life. There is a most exalted contrast, and, at the same time, an evident fitness, in the circumstance that the same organ which is the instrument in the hands of the Almighty to build up the wondrous and upright structure of his own image, is the very one he has also chosen to sound his praises, and make him known on earth."

The lecturer next proceeded to treat of the development and structure of the teeth; and this portion of his subject was illus-

trated by a variety of splendid diagrams. The teeth may be said to be formed by a re-duplication of the mucous membrane of the mouth called the pulp, which Mr. N. has discovered to be composed of cellules or vesicles, in which the ossific matter of the ivory is deposited: the ivory is, therefore, neither more nor less than ossified pulp. Of the reticular or formative surface of the pulp, the lecturer here exhibited some particularly interesting coloured drawings. With respect to the ivory, the doctrine of Liewenhoeck, that it is tubular, has lately been revived; but Mr. Nasmyth stated that, according to his researches, the fibres of the ivory were baccated, and presented the appearance of rows of beads, as he shewed in various drawings. The interfibrous substance he had also discovered to be decidedly cellular. When the growth of the ivory is completed, the primary function of the pulp ceases; but its residue Mr. Nasmyth has often observed to ossify under the influence of disease in the higher animals, and normally in the lower. Interesting examples of the normal occurrence of this irregular osseous formation are presented by the teeth of the sloth family; and those of the fossil megatherium are very interesting examples of it. It occurs generally in the teeth of all fishes, in the walrus, and many others. Mr. Nasmyth has thought it worthy of being ranked as a distinct fourth tooth-bone substance. The enamel which surrounds the ivory he has discovered to be distinctly cellular, and characteristically so in different animals. He has also traced on the surface of this substance a capsule, which had escaped the notice of preceding writers. A coating has long been observed, and acknowledged as most obvious, on the grinder of the elephant, where it fills up the spaces, which would otherwise be unoccupied, between the layers of enamel, cementing the whole of this convoluted compound-tooth into one solid mass. It is to be observed in all teeth of this kind, which are required to perform the office of a grinding-stone in pulverizing the food: and this substance is provided in order to fill up the interstices, and that there may be produced a succession of surfaces efficient for that purpose. The surface presents three substances in succession, differing in texture, hardness, shape, and disposition. The enamel is, of course, the hardest, and presents a beautiful undulating edge. The process of trituration wears down the ivory on the one hand, and the cement on the other, these being of softer texture than the enamel, and thus an irregularity of surface is necessarily produced. The cement being again a little softer than the ivory, a most efficient grinding surface is kept in constant order by the very act and habitual exercise

of the function of mastication. This beautiful adaptation of means to an end, is only a single instance of the design which is demonstrated in every part of the machinery of the mouth. Mr. Nasmyth stated, that, in pursuing this inquiry, he had found, that this capsule of *crusta petrosa* is present in an attenuated state, and can be demonstrated in a great number of teeth, which have been hitherto considered devoid of any covering at all external to the enamel.

The lecturer concluded his eloquent discourse, by showing the importance of the study of the teeth in geology. From their being so characteristically organised in different animals, he said, they became much more valuable guides than fossil bone. Certain fragments of fossil remains can be demonstrated to perfect conviction to be fragments of teeth; and, from examining these by the microscope, they can be proved (so typical is their structure) to have belonged to animals of a certain order and conformation. Put in possession of this scrap of information, we can further proceed to delineate the animal in each particular case in all its details, with a degree of certainty nearly mathematical. From this knowledge follows necessarily an idea of the country or locality in which alone the animal, thus restored, could exist; and hence, from an examination of minute, insignificant, and, to common observers, utterly worthless fragments of tooth-bone—from slight particles of crumbling matter—we derive the means of contemplating whole regions of the face of the ancient globe, covered by its animal tenants.

Mr. Nasmyth finally said, that he had been led to the study of the structure of the teeth, from his having considered it his duty to investigate the novel doctrines which had been lately propounded, in the hope of their throwing new light on maladies daily passing under his notice. And this duty, like all others which are executed with willingness and alacrity, had been to him a source of unmingled gratification; for, in performing it, he had not only been rewarded by arriving at a comprehension of many phenomena of disease which had been hitherto obscure, but had been so fortunate as to establish results which would, he hoped, constitute some advance in this department of anatomical science.

LIVERPOOL MEDICAL INSTITUTION.

DR. FRECKLETON IN THE CHAIR.

Mortality of Liverpool.

DR. DUNCAN stated, that in consequence of public attention having been lately

drawn to certain remarks which had appeared in various newspapers, on the great mortality of Liverpool, compared with that of other large towns, he thought it proper to bring the subject under the notice of the meeting. The remarks alluded to were founded on the statements made by Mr. Farr, and published in the first annual report of the registrar general. These statements, however, it should be known, referred to the limited period of six months only, viz., the latter half of the year 1837, a period much too short to justify the deduction of any general inference.

During that half-year it was true the mortality of Liverpool was very great, being as high as 1 in 28, while in Manchester it was only 1 in 38, in London 1 in 36, in Birmingham 1 in 45, and in Leeds 1 in 55. But it so happened that the period in question was the most unfavourable for Liverpool, and the most favourable for the other towns, which could possibly have been selected for a comparative statement of mortality.

In 1837 we were visited by three epidemics: influenza early in the year, and subsequently by typhus fever and small-pox, the latter having been more prevalent and fatal than in any former year, perhaps, since the introduction of vaccination, and having caused nearly one-fourth of the whole number of deaths occurring between the 1st July and the 31st December. The burials within the parish of Liverpool, during the year, exceeded by 1000 those of any other year on record, not excepting 1832 and 1833, when the cholera was epidemic here. The deaths from epidemic diseases generally, during the latter half of 1837, amounted to 34 per cent. of the total number of deaths: while in Manchester they amounted to only 24 per cent.; in London to 26½; in Birmingham to 17 per cent.; in Leeds to 18 per cent.; and in the kingdom generally to less than 22 per cent. In Liverpool, with a population less than one-sixtieth of the population of the kingdom, the deaths from small-pox formed nearly one-ninth of the whole number of small-pox deaths throughout the kingdom; while the deaths from typhus fever amounted to nearly one-seventeenth of the whole deaths from that disease. London and Manchester come nearest to Liverpool in the mortality from typhus; but in neither of these towns was the proportion much more than one-half that of Liverpool, as compared with the population. But the most convincing proof of the fallacy attaching to conclusions drawn from limited data, are to be found in a comparative statement of the mortality of Liverpool and other towns during the half year subsequent to that which had been selected by

Mr. Farr, viz. the first half of 1838. During this period we find, from the same returns, that the mortality of Liverpool had fallen from 1 in 28 to 1 in 34; while that of Manchester had increased from 1 in 38 to 1 in 31; that of London, from 1 in 36 to 1 in 31½; of Birmingham, from 1 in 45 to 1 in 36; and of Leeds, from 1 in 55 to 1 in 45: so that, during this half year, the mortality of Liverpool was actually lower than that either of Manchester or London, and very little higher than that of Birmingham. It was also considerably below that of Edinburgh, and very much lower than that of Glasgow: the mortality of the former, during the twelve months between May, 1837, and May, 1838, having been 1 in 29, and that of Glasgow 1 in 24.

Rupture of the middle Meningeal Artery.

Mr. Craig related the following case:—In the month of December, 1838, a man, apparently about 50 years of age, was carried into the North Dispensary by two policemen, who had found him lying on the street in a state of insensibility, occasioned, as they supposed, by his having been knocked down by a car.

The skin above and around each eye was severely contused, and much swollen. He had been placed on his back, and was breathing calmly. His breath had a strong alcoholic fœtor. When spoken to sharply, he muttered a word or two, and immediately relapsed into his former state; he threw up his legs, on being pinched: there had been no vomiting. In the course of half an hour he became more sensible, and when disturbed would raise himself into a sitting posture.

I then had him conveyed to the Northern Hospital, where he remained for eight days, after which time I again saw him. Upon inquiry, I learned from Mr. Arnott, that he had remained in the state in which I first saw him till the following morning, when he had got out of bed, and seated himself by the fire. On being spoken to, he looked up with a vacant stare, said nothing, and returned to bed. He then began to manifest symptoms of aberration of mind. At one time he was so violent, that he had to be tied to the bed; at another so calm and rational, that he was allowed to walk up and down the ward. All this while (a period of six days) his mouth and tongue were foul, and his bowels obstinately constive. He presented all the appearance of a person in an advanced stage of typhus fever.

On the seventh day after the receipt of the injury, his wife having called to see him, he requested to be taken home; and, with her assistance, accomplished it, a distance of a mile, in the course of an hour and a half: he was then sensible, with the

exception of now and then making an insane remark. Next morning he got up, dressed, and went down stairs; when he was again observed to be more insane. Shortly afterwards he undressed himself, and went to bed, where he was found soon afterwards in a state of stupor bordering on insensibility.

When I saw him on the following morning, (the 9th), he lay on his back in a state of stupor, muttering incoherently, and occasionally yawning; his arms were rigidly bent, and he appeared very much averse to their being extended. The contusions on his face had nearly disappeared; but there was a small scab over what had been an abrasion on the right temple. His mouth and tongue were foul, and coated with a dark, slimy mucus; his gums appeared slightly affected with mercury; and his breath had its factor: his pupils were dilated; his bowels were costive; had passed water freely. Pulse small and rapid.

10th, Much the same.

11th, Erysipelas had attacked the face, commencing at the abrasion on the right temple. He was now more sensible; and, on being asked where he felt pain, he put his hand to the left side of his head.

12th, Erysipelas extended all over face and forehead. Rather more sensible.

13th, Erysipelas declining; perfectly sensible; complaining of acute pain in right knee, which he said was caused by the wheel of the car, by which he had been knocked down, passing over it. Shortly after my visit he became again insensible; in which state he continued for about three hours, and died.

On dissection, seventy hours after death, — Cellular substance, under scalp, ecchymosed (filled with blood) throughout nearly whole extent; and, on laying open skull, a fracture was found, extending along the whole course of the left squamous suture, and depressed about three lines. Upon the dura mater, covering the fore part of the anterior lobe of the left hemisphere, there lay about an ounce of coagulated blood, alongside of which was a cavity or depression which might contain a hen's egg. Blood had evidently proceeded from the middle artery, which was torn across. Between the folds of the arachnoid, the superior surface of the left hemisphere was covered by a thin layer of blood, and the veins of the pia mater under this were highly engorged. The base of the middle lobe of the right hemisphere was broken up and softened, the consequence of laceration, to about the size of a pigeon's egg, and appeared a red pulsataceous mass. The whole of the brain was more vascular than usual, but there was no lymph effused on any portion of the arachnoid.

On laying open the right knee, about

two ounces of pus, mixed up with a little synovia, was found in the cavity of the joint. The synovial membrane was injected in several places, but there was no ulceration.

THE LIVING SKELETON.

FROM a notice of the sittings of the Royal Society of Medicine of Bordeaux, published in *Froriep's Notizen*, October, 1839, it appears that the man, Ambrose Claude Saurat, who, some of our readers may remember, was exhibited in this country about 15 years since, is still a living skeleton. He has lately been carefully examined by the Royal Society at Bordeaux. From their description of him it appears, that except in a partial loss of the use of his extremities, his condition has not materially changed. He can still breathe freely, and has no particular pain about the chest. He digests well, and never has diarrhoea, though he is sometimes constipated. His appetite is tolerably good, but he eats little, and adopts a very regular regimen. He prefers the flesh of young animals, and avoids pickled meat, wine, and spirits. His daily consumption of food is only 12 ounces.

Saurat's intellectual faculties are still good: but his memory has decreased for many years. His sexual appetite is still undeveloped, and he has never had any intercourse with women. He enjoys quietude, and has no cares or mental suffering. He often has singular dreams; in which he hears music, and thinks he is actively exerting himself. He sweats profusely at night, and especially after drinking cold lemonade. He cannot bear a dull heavy atmosphere; but the climate of Italy exactly suited him.

The deformity of his hands and feet (and he can now neither walk nor stand), was preceded by dragging pains in his extremities, which commenced 10 or 12 years ago. The power of moving them was gradually lost; but he had no pain in the head or back, nor any remarkable pain in the abdomen.

After Saurat had been examined, and had given the account of himself, from which the above is abstracted, in a very clear manner, his abnormal condition was more accurately inquired into.

His head is a little turned towards the right side: his eyes have a quiet dull expression; his complexion is pale and fixed; the left side of the face is thinner than the right; the mouth is large, and the right corner of it is remarkably drawn downwards.

His chest has a deep depression on the median line; the ribs, and especially those on the left side, are very much curved; the antero-posterior diameter of

the chest is about 4 inches; the spine is very much curved to the left side, but the curvature alters according to the mode in which the trunk is supported. Percussion detects a fuller sound on the right than on the left side; and there is a slight dulness on the left side behind. With the stethoscope, the respiratory murmur can scarcely be heard on the anterior and right side of the chest: but on the left one hears even without the unassisted ear a distinct rubbing sound. The respiration is chiefly effected by the abdominal muscles, for the ribs scarcely move. He inspires 24 times in the minute; his radial artery beats from 80 to 84 times in the same period.

His abdomen presents nothing peculiar; it is yielding and tolerably normal in its development and form.

In the genital organs, nothing marked is to be observed.

The extremities are incredibly emaciated, especially the hips, thighs, shoulders, and upper arms. His hands and feet are curved and swollen; the fingers are hook-like and almost immovable.

Saurat has got together a respectable property, and has a small estate in the district of Mans, where he takes care to pass the winter.

COLLEGE OF PHYSICIANS' DEGREES.

To the Editor of the Medical Gazette.

SIR,

I AM induced to request you to insert these few lines, in order to do away with a very prevalent notion concerning the recent regulations of the College of Physicians. Many of my acquaintances, and I believe many others in the profession, still have an idea that it is necessary to graduate at some university before applying for the license at the College. Now it ought to be generally known, that the College can and do grant the *degree and title* of Doctor of Medicine, to those who pass examinations for licentiates or extra-licentiates, whether they have obtained degrees elsewhere or not; and that the College possess this power by as clear and legal right as any university in the kingdom. This is, however, not generally known, and a friend of mine who recently graduated at Edinburgh, assures me he would never have taken the trouble if he had known it could be done in London. I need not point out the advantages of obtaining a degree from an institution which gives at the same time a legal title to practice.—I am, sir,

Your obedient servant,

M.D. EDIN. ET LEYDEN.

Strand, April 16th, 1840.

MR. MAYO.

To the Editor of the Medical Gazette.

SIR,

WILL you have the goodness, by publishing this note, to afford me the opportunity of disavowing the having authorized the proprietor of Holloway's ointment to use my name in his advertisements, and of mentioning, that having made trial of this preparation, I do not believe it to be more efficacious than any other of the detergent ointments that are in common use.

I am sir,

Your obedient servant,

HERBERT MAYO.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.
Surgeon to the St. Marylebone Infirmary.

DISEASES OF VEINS, *continued.*

VARICES — *their Nature — Varieties — Treatment by Compression — Ligature — Incision — Caustic — Needles — Extirpation.* — MUSCULAR AND TENDINOUS SYSTEMS — *Wounds — Contusion — Ruptures, Retractions, and their Treatment.* — CLUB FOOT — *Nature — Variety — Modes of Production — Modes of Treatment.*

VARICES.

Nature. — A varicose condition of the venous system may exist at any part of the body, but is most commonly seen at the lower extremities. The state may be a simple dilatation, without any very evident change of structure or loss of contractility; it may consist of uniform dilatation with thickening, when the vein presents certain of the characters of an artery, and remains open upon section; it may consist of an unequal dilatation, with thickening or thinning, and the valves may be partly destroyed.

Symptoms. — The condition is characterized by certain external signs; the veins may resemble projecting knotted cords, straight or sinuous, variable in size, usually soft to the touch, not ordinarily accompanied by any considerable change in the skin over them; sometimes, however, it is bluish; sometimes bronzed; they increase in size under exertion, and the vertical position, rapidly diminish, or gradually disappear under pressure, or the horizontal position. Strictly speaking these are varices; but under the same

term have been included lobulated or knotted tumors, with large bases, irregular form, soft consistency, violet colour, not unlike a bag of leeches or earth worms—these are varicose tumors.

Where the dilatation is uniform, for some time there is no apparent change of structure either in the parietes or the valves; the vein does not become sinuous, nor unequally thinned, but preserves a thickness proportioned to the size of the vessel: this condition scarcely merits the name. But this enlargement may be accompanied by thickening, and this state is often well seen in the trunk of the saphena—rarely in its branches: we then find this vein forming from the groin to the lower part of the leg an uniform projecting cord, as large as a turkey quill, round, resistant, almost straight, presenting only a few windings. The calibre of the canal is augmented, and, when a section is made, it remains open: the internal membrane is not thickened; it is the middle tunic, if so it may be called, which is thickened, and gives to it its artery-like character. When the dilatation is unequal, with change of structure, the disease is most commonly found to affect the saphena trunk at the lower part of the thigh, the leg, and its branches; the vessel, in this case, is alternately enlarged and constricted. If we hold a vein in this state between the eye and the light, it is evident that the thickness is unequal; extremely thin at some points—very thick at others; but the vein is cylindrical. When the vessel becomes sinuous, it resembles somewhat the character of the colon, and the valves undergo great changes, they do not extend so far across the vessel, and, at their bases, there are often to be found sinuses not unlike those above the valves of the aorta. As the disease proceeds, the curvatures increase until the vessel may acquire double or triple its natural length. The internal tunic is then

thickened, the valves more or less completely destroyed. These sinuses or pouches increase in size, and occasionally contain coagulated or fluid blood: this may depend upon the development of chronic inflammation. The cellular tissue around the vessel is indurated; sometimes, indeed, though rarely, it is transformed into a cavernous or erectile tissue.

In the order of frequency of the occurrence of the disease, the internal saphena takes the first place; then comes the external, which does not ordinarily suffer until the internal has been some time affected; the veins of the pelvis, those of the spermatic cord, the rectum, the scrotum, the labia, &c. The disease usually affects different branches of the saphena—rarely at the same time do the whole of the subcutaneous veins of a limb suffer; it usually exists at the same time in both legs, but unequally. I have found the disease most frequent on the right side, in the proportion I have already indicated in a former lecture. The greater number of cases of partial dilatation of the saphena trunk are seen in muscular men, in whom the circulation is energetic. The disease is rarely seen in children; at the time of puberty it is apt to be manifested; but between thirty and forty is the most common period of its occurrence—a period when men take strong exercise, and women have borne children; after that it becomes so common, that out of a hundred very old persons you will not see above seven or eight without it. Briquet says, of fifty men, all under thirty, whom he examined, he found four varicosed; of thirty women, under thirty, he only found one varicosed; of sixty men, passed thirty, he found fifteen; and of ninety-three women of the same age only twelve; of a hundred and fifty-eight old men, he found fifty-three, and, of three hundred and ninety old women, he found only thirty so affected. It is, therefore, shewn that the disease is more frequent in man than woman, since, of two hundred and fifty-eight men, there were seventy-one varicosed, while, of four hundred and eighty-three women, only forty-two were thus affected. In man it principally affects the trunk of the saphena and its larger branches; in woman, the cutaneous branches. The vertical position tends more than any other circumstance to this condition, therefore it is more frequent in the poor than the rich: soldiers, painters, porters, waiters, washerwomen, cooks, are particularly exposed to the disease.

Among the efficient causes are the lateral pressure of the column of blood, which is increased by the vertical position, contusions by which the venous parietes may be enfeebled, abdominal tumors, obesity, gestation, ligatures around the limbs,

which interfere with the venous circulation, and other causes to which I particularly alluded when speaking of varicose ulcers. It has been said that the disease increases with age: this is true up to a certain point, but when people get too old to labour, then the dilatation is lessened.

The disease may commence in any region of the limb: in a strong man it may begin in the thigh, and very gradually finds its way down the leg; oftener it begins in the feet and legs. When moderate, it occasions little inconvenience, but when considerable, the numbing sensation which it occasions is often very great.

If we incise a large varix, the vein is quickly emptied up to the next valve; at another time, if in a varix we tap upon the vein in the thigh, an undulation may be discovered in the middle of the leg. In varices, if we make a section, the blood is often scarlet; the jet is strong, sometimes interrupted.

When the vessels of a limb have been long varicosed, the adjoining cellular tissue becomes indurated, the legs are tumid towards evening, and are hot and painful: in the labouring classes the skin is hardened, the cellular tissue lard-like, the limb cold, hard, and pasty, as large below as above, and it has great tendency to ulcerate. The ulceration does not extend above the knee—what is the cause of it?

The condition may give rise to phlebitis, especially when there is ulceration, or when a varix has been contused. It may give rise to the development of phleboliths: this name is applied to small concretions which are met with in the interior of veins, and which are formed of whitish concentric strata; they are round, and vary from the size of a millet seed to that of a pea. They are usually found in the diverticula or dilatations of the veins, and are, it is believed, formed by fibrine.

Veins in this state may be perforated: this may happen during gestation, but rarely during a first, and generally in women whose occupations oblige them to stand long. The part where the vein gives way is usually not far above the inner ankle. In some persons it is preceded by slight pain and symptoms of superficial inflammation. In others, a round spot is presented; it enlarges and becomes ecchymosed, ulceration takes place, and the vein is opened. During an effort all gives way, and blood flows, sometimes by an oozing, sometimes in a jet, though the opening is hardly perceptible, and slight compression suffices to arrest it. This state is, as we have already seen, a frequent source of ulceration.

Treatment.—In the treatment of this disease many means have been employed; Hippocrates pricked them, Celsus recom-

mended that they should be cauterized, or removed with a cutting instrument, Ætius speaks of cauterization and the ligature, other persons have recommended compression; but the greater number have counselled excision. Modern authorities have advised palliatory means.

Compression has been more largely employed for this purpose than any other agent; but, whether in the form of a laced stocking, or a bandage, it must be used for many years, and even then may leave the patient no better than it found him: it is difficult to maintain it equably, and, failing that, it will be injurious.

The *ligature*, recommended as we have seen at a very early period, was abandoned, until Home, Carmichael Smith, Travers, Physick, and Beclard, again brought it into notice: they believed that no reasonable apprehension need be entertained of its occasioning phlebitis, but a contrary opinion so universally prevails that in this country it is rarely employed at present. The consequences of the ligature are obliteration, and the passage of the blood along adjoining branches. The circulation is as much more easily carried on, that there are two orders of vessels through which the venous blood may circulate. After the ligature many patients complain, for some days, of feeling the blood mounting up, and distending the veins near the ligature, but that soon ceases, and the subcutaneous veins become distended. At the moment of tightening the ligature, pain is felt, slight inflammation is developed at the edges of the wound, and trifling suppuration, an uneasy tensive creeping sensation is experienced from the point where the ligature is applied to the lower part of the limb, and, for four or five days, the vein continues tense; this gradually subsides, and the blood coagulates. The ligature very rarely comes away before the sixth or after the twenty-second day; usually it happens between the seventh and the fourteenth day; the wound soon cicatrises after the ligature comes away, the veins contract, and, by the end of a month, they are small and solid, containing a coagulum which is ultimately completely absorbed. All these circumstances pass in the inferior extremity, as to the superior, the blood escapes at the moment the section is completed; moderate inflammation is developed, the parietes are thickened, contracted, and ultimately disappear. In some cases, at the end of a few months, the varices which had disappeared return, but are much less troublesome than before. This may be owing to the ligature having been applied close to a joint where collateral veins joined the trunk, the circulation continuing, the formation of a coagulum is prevented.

Transverse incision of the vein has been employed to a considerable extent in this country, with the idea that the dangers and inconveniences of the ligature might be thus avoided. But it was shewn that this object was not attained. Brodie, believing that the want of success was owing to the vein being exposed too largely, proposed that a narrow knife should be passed under the vein, and the section should be made without exposing it; and to render this more certain the integument was to be drawn aside when the puncture was made, so as to produce a want of parallelism between the external wound and that of the vein. Experience, however, has shewn that, whether the vein be exposed or not, phlebitis may supervene. The ancients were accustomed to make an incision through the whole of an agglomeration of veins; and it is said that accidents were unfrequent.

A plan in common use at the Middlesex Hospital, is to apply upon the course of a varicose vein a composition of caustic potash and soft soap. It is left until a large slough is formed, and if the vessel be superficial, that may be included in the destruction, if not, adhesive inflammation may be developed in it, and its cavity be obliterated. This mode, however, is not exempt from the danger of suppurative phlebitis.

Some years ago, Davat proposed that veins should be obliterated by passing needles under them, and twisting threads tightly under the needles. The operation has been variously modified by Velpeau and others, and is, in my opinion, a successful operation. It has been performed very frequently, and I know of only two accidents, and they happened in persons whose general health was bad. The mode in which I perform the operation is to choose a large varicose trunk, to pass one or two needles under it: if the latter, I leave an interval of an inch or more between them. I then twist a ligature around, not tight enough to strangle the tissues and cause an ulcer, but merely tight enough to prevent the blood from circulating. At the end of six, seven, or eight days, I remove the ligature, and I am mainly guided as to the time of the needles becoming loose, by a little purulent oozing taking place around them. At first, the portion of the vein below the ligature is distended, but at the end of three, four, or five days, this is materially lessened, a coagulum is formed, and the vein feels firm. If two needles be inserted, a certain quantity of blood is included between them; and when this feels quite firm, we may safely remove the needles. Extirpation of varicose veins is rarely practised in the present day; it consisted

in circumscribing a varicose tumor between two incisions, and dissecting out the mass. This operation was often long and painful, and subject to the same accidents as section by other methods.

MUSCULAR AND TENDINOUS SYSTEMS.

Muscular.

Wounds.—When a muscle is cut through, the two ends are removed as much farther from each other as the person is energetic and the muscular fibres longer. It is increased still further if the position given to the part be one of extension. In treating these wounds, therefore, care must be taken to place the part in the most advantageous position, and to avoid all which can irritate it. Muscular tissue is not reproduced, coagulable lymph is deposited between the cut surfaces, it is organized, connects the extremities, and is gradually transformed into a fibro-cellular tissue, not unlike the tendinous intersections which exist on the rectus abdominis muscle.

Contusions of muscles offer this peculiarity, that they may not only give pain, but may produce paralysis; and this is especially marked in the deltoid and glutei muscles, where it is often extremely obstinate, and sometimes exists in defiance of all the means which are employed.

Rupture.—Well-authenticated examples of this accident are not to be found before the middle of the last century. Many persons still cling to the opinion that it is the tendinous, and not the muscular fibres which give way; but the cases described by Sedillot are too many and too exact to allow us to doubt that the muscular and not the tendinous fibres were implicated. These injuries are owing to a sudden and unexpected effort, in which a muscle is placed in forced contraction, whilst the rest of the organ is in a state of relaxation. Of the twenty-eight cases referred to, the seat of injury is indicated in twenty-one: thirteen times it occurred at the point of insertion of the muscular fibres into the tendon, eight times it happened in the body of the muscle. The muscles most exposed to rupture are those of the calf of the leg, the rectus femoris, the rectus abdominis, psoas, and deltoid.

The sudden and involuntary contraction which causes rupture, is usually interrupted by an acute pain or shock, which indicates the moment of rupture. If the patient be left to himself, this pain may continue, with more or less severity, for some time. Often a noise has been heard at the moment, like the cracking of a whip; when much of the fibres of a muscle have given way, a depression exists at the point, frequently this depression disappears soon, the effusion of blood and

tumefaction filling it up. Left to itself, it may be many weeks or months before it is cured, and when accomplished, it is by the means described when speaking of wounds of muscles. Usually these injuries have not serious consequences, but Sedillot and Bover mention the case of a young man, who, in lifting a load, ruptured the psoas muscle: the accident was followed by inflammation, abscess, and death.

The proper mode of treating these accidents is by position, rest, and bandaging. The position must be such as to relax, to the greatest possible extent, the injured muscle, and it should be retained in this position for ten days or a fortnight. A bandage should, if practicable, be applied, so as to support, equably and firmly, the part. Compression favours the relaxation of the muscle, keeps the edges more in contact, is opposed to new contractions, and facilitates the absorption of the effused fluids. With a bandage well applied, in the case of rupture of the extensor muscles of the foot, the patient may at once move about. If there be much inflammatory action, local or general bleeding and cold applications may be necessary.

A muscle may, it is said, be *luxated*—that is, it may escape from its fibrous sheath. Pouteau believed it frequently happened (*Mélanges de Chir.* p. 405), but certainly the single case he mentions is not calculated to carry with it much conviction on the subject. Portal mentions those cases which he had observed in the dissecting-room. A certain number have been observed in the dissecting-rooms of London, principally affecting the long head of the biceps. Whether these cases were produced by the violence of dissecting-room porters, or whether they existed during life, is doubtful. If, by the accident, the aponeurotic sheath were opened, no doubt a muscle might escape; but whether under any other circumstance, may fairly admit of doubt.

Retraction.—When we examine a retracted muscle, the fibres have become white, and almost reduced to a condition of aponeurosis. Sometimes there is no great diminution of bulk, at others it is considerable: sometimes the shortening is equal to a fourth, a third, or even half the length of the muscle. The consequences of this condition are flexion of the part, and often a vicious conformation of the parts to which it is attached. This deformity will be much greater if the condition has existed from infancy; but this we will particularly consider when speaking of wry neck and club foot.

Tendons.

Wounds of tendons may happen in various ways—either in the progress of a sur-

gical operation or by accident. If the tendon be protected from the action of the air, one of two things happens: if the parts be nearly or completely in contact, the part may heal by first intention; if removed to a certain distance, a plastic lymph is developed, connects the extremities, and ultimately acquires all the characters of tendon. If the interval be considerable, the tendon will be lengthened by so much, and great inconvenience may be the consequence, because the muscle to which it belongs becomes, as it were, paralyzed and useless. If the extremities of the tendon be in contact with air, they become pale; but at last, after a kind of exfoliation, the surface becomes vascular, red, and covered with granulations, by which union is ultimately accomplished. In these cases, the means by which we can bring the parts into more direct contact are to be preferred: the suture would appear to accomplish best this indication, but it necessarily irritates, so that if it can possibly be done without, it should be dispensed with. Velpeau speaks of a case where there was a space of four fingers' breadth in the rectus tendon, without sensible inconvenience in extending the limb: where great precision in motion is necessary, under similar circumstances, inconvenience would be felt. It is, therefore, difficult to recommend or reject absolutely the use of the suture, but I agree with Mondiere, who says it is sometimes useful, rarely indispensable, and very frequently useless or injurious. If we determine to use it, we must select very sharp needles; because tendinous structures are very resistant. The position must necessarily vary with the kind of tendon divided: if extensors be divided, we completely extend the limb, if flexors, we moderately flex it, if there be a wound of the integument, we endeavour to heal it. In most cases, careful bandaging above and below the wound will be found useful, and for fourteen or fifteen days the part should be kept entirely at rest. If the wound of the tendon be jagged, it should be made regular, if the tendon be small, one suture will suffice, if broad more will be required. The ligatures must usually be cut away when their presence is no longer necessary, for we shall wait a long time for them to cut their way out.

The tendons in the neighbourhood of the elbow-joint are sometimes wounded; the triceps behind, the biceps in front. The division of the tendon of the biceps interferes less than might be expected with the motion of the forearm. Gangrene and deep ulceration have destroyed part or even the whole of this tendon, and yet the power of flexion has been gradually restored. Haller, Dionis, and others, relate

cases of rupture, or section of it, where the movements of the forearm were scarcely at all interfered with. In 1836, Velpeau saw a printer who had a large contused wound near the bend of the arm: there was division of the skin, of the aponeurosis, of the whole of the biceps tendon, and even part of the brachialis anticus. Velpeau said, if amputation could be avoided, flexion of the forearm must be lost; and yet the movements of the forearm were almost completely restored. After the division of the biceps, the brachialis anticus, to a certain extent, performs its functions. Still no efforts should be wanting to heal these wounds; and if the separation be great, and position be insufficient to bring the ends together, the suture may be necessary. In Severinus (*Med. Effie. de Bonet*, p. 593) is a unique case of wound of the biceps, but it is very vaguely described: if we consider the cases of fracture of the olecranon, we shall come to the conclusion that it may not occasion very serious derangement in the motion of the forearm.

The only wounds of tendons of the foot which we shall particularly consider are those implicating the tendo-Achillis. Incomplete division of this tendon may occasion serious accidents. A scythe incompletely divided this tendon; great pain, severe fever, and delirium followed, and these symptoms were promptly subdued by completing the division. (Molinelli). Bazzieu mentions a case where the section was almost complete; the pain was acute, the tension very great; both were dissipated by cutting the remaining fibres. Clement details a case, where three-fourths of the tendon were cut through; inflammation, gangrene, and hydrophobic symptoms were developed, but speedily ceased when the tendon gave way. These facts are, however, insufficient to justify us in recommending the system pursued by the ancients. No matter how slightly the tendo-Achillis was wounded, their rule was to complete the section. Besides, a large number of cases of incomplete division are related where no such accidents occurred. Abandoned to themselves these wounds would heal, but the tendon would be lengthened. As, however, the functions of this tendon are of first-rate importance, we must always endeavour to procure apposition, so that no serious lengthening may occur. This may be procured nearly as well without suture as with. The following attitude, in which the leg is to a certain point flexed, and the foot extended, will very well and very easily accomplish the object, unless there be actual loss of substance. The older surgeons were accustomed to maintain a limb in this very uncomfortable position for several months.

Towards the end of the second or third week we may begin to move the limb: at first the motion should be very limited, but extension of the tendon is to be gradually made.

I know no case where, by accident, the biceps femoris has been divided, but there are cases on record where the tendons, forming the inner ham-strings, have given way, and where suture and position have restored, to a certain extent, their functions. Boucher mentions a gun-shot wound, which implicated both orders of flexors of the leg, and yet the power of flexion was fairly restored. Paré describes a case mentioned to him by a barber-surgeon. "There was total incision of two tendons which flex the leg; by means of suture the ends were brought together and perfectly consolidated." In a situation like this one would think the ends might be brought together without suture. The best position in such a case would be that in which the leg is flexed, and the thigh extended.

Rupture.—Tendons are more frequently ruptured than muscles; but this is a matter open to discussion, because the point injured is usually that in which it is difficult to say, really, which has suffered—the point of apparent junction in fact. It is commonly a consequence of violent muscular contraction, such as is produced in the act of jumping: such are the ordinary causes of rupture of the tendo-Achillis. Sometimes it may happen without violent contraction; a false step, or missing a step in coming down stairs. In these cases the organs are, as it were, taken by surprise; and a more moderate effort is then sufficient for the purpose. The rupture of certain tendons is accompanied by a noise which the person himself hears; a sensation of percussion or pinching is felt, as if a stone were thrown, or the part were cut by a whip. The pain usually soon abates, but a numbness continues longer. The importance of these injuries is proportioned to the importance of the injured tendon; the rupture of the tendo-Achillis, that of the rectus femoris, the triceps brachialis, are the most serious.

The treatment of ruptured tendons is the same as that of wounds; and, therefore, I need not further allude to it.

CLUB-FOOT.

Club-foot, though it expresses no particular condition of that organ, is well known

as a term applied to deformities of the foot, which are often of frequent occurrence. Those deformities have four great varieties, which are distinguished by the terms *varus*, *valgus*, *talus*, and *pes equinus*: *varus* is a forced adduction; *valgus*, a forced abduction; *talus*, forced flexion of the foot upon the leg; and *pes equinus*, an extension carried to the highest degree.

In the case of *pes equinus*, the gastrocnemii, soleus, and the flexors of the toes, are retracted; in *varus*, the tibialis anticus; in *valgus*, the peronei; in *talus*, there is retraction of the tibialis anticus and the extensors of the toes, with paralysis and atrophy of the gastrocnemii and soleus. These are primary forms of club-foot, but one variety may often partake of others, so that the pure and simple form of either variety is not often seen. Simple *varus* is so rare, that, in 400 cases of club-foot, Guérin only saw it seven times. Simple *valgus* is still more rare; and *talus* is very rarely seen at all.

In a considerable number of cases, club-foot is a congenital disease; and, being produced under circumstances in which it is impossible to observe its progress, the mode in which it is brought about has been the subject of much discussion: some persons thinking that there must be a pre-existing vice in the germ; others, that there must be a mechanical cause, to which the limb is subjected in utero; others referring it to some accidental disease in the fœtus; others to arrested development; and others to irregular muscular action.

Whether a vice can exist in the germ I do not pretend to say; certain it is, there are many examples in which the disease seems to have been hereditary. Brückner mentions the case of a man who had two club feet: three children were born to him with the same infirmity, a fourth was born with straight feet; he immediately suspected his wife of infidelity, and discovered it.

From the time of Hippocrates to the present, it has been maintained, that the pressure of the uterus might cause this deformity. We know that external pressure, long continued, may change the relation of articular surfaces, but it is extremely difficult to bring proofs that this is really a cause of club foot; and the presence of the amniotic fluid has been urged as an objection against it. Martin maintains, that in most cases of club-foot the quantity of that fluid is small—insufficient to prevent the pressure of the uterus; and he brings forward cases as evidence of this fact, where the direction of all the limbs affords a strong presumption in favour of this opinion.

Joerg is among the first who attributed club-foot to the excess of action of certain

muscles, which may depend upon some lesion of the nervous system. Delpech believes those muscles to have been primarily short. Jalade-Lafond believed that convulsions, to which the infant may be subject during uterine life, might cause it. Rudolphi believes these deformities to be dependent upon a morbid influence of the nerves upon the muscles.

Whether deranged muscular action be the exciting cause of these deformities is a matter almost, if not altogether, incapable of proof; but there can be no doubt that when displacements exist the muscles accommodate themselves to new circumstances, and then may oppose themselves to reduction. Although, therefore, I must not be understood as coinciding in the opinion, that each particular deformity is produced by the retraction of particular muscles, I admit that it is necessary to overcome the resistance of certain muscles in the cure of the disease—the tendo-Achillis, to let down the heel; the tibialis anticus, to allow of the sole being turned to the ground; the tibialis posticus, which turns inwards the fore part of the foot; the peronæi in certain outward deformities. How this resistance is to be overcome we shall presently consider. The theory of arrested development seems to me to depend upon this question: in the healthy condition is there any period of uterine life when the infant has always club-foot? if not, arrested development does not explain it.

Club-foot may be developed during the existence of convulsions in infancy, and the period of dentition; it may happen as a consequence of burns, of abscesses, and of various other injuries and diseases.

The disease appears to have a greater predilection for boys than girls, and this circumstance has been taken advantage of by Martin: he says boys are larger, and more exposed to be compressed by the uterus. Of 198 cases, 84 were double, and 116 occurred in boys.

Whether congenital or acquired, in appearance the deformity is very similar: there is emaciation of the leg, and more especially of the calf; still it often retains its natural form; sometimes the tibia is curved, and the internal ankle no longer projects. As the muscles are short and thinned, their tendons seem elongated; the skin of the points of the feet which touch the ground is callous, and occasionally a bursa is developed in the cellular tissue as a protection. It is hardly necessary to insist on the great inconvenience which a patient with these deformities suffers.

Treatment.—It has been asked, are these diseases ever cured without the intervention of art? Many cases are on record, where the necessity of carrying heavy burdens has

obliged the patient to rest firmly on the sole of the foot, and he has ultimately got rid of his infirmity. Richter mentions the case of a young man with club feet who became a tailor; the habit of resting the thighs upon the feet, in sitting cross-legged, ultimately relieved him of his infirmity. But cures by such simple means are rare, and they require a great deal of time.

There is one means which has been largely employed by Dieffenbach and Guerin, and which is in many respects less objectionable than ordinary machines—I allude to plaster of Paris. The limb to be acted on is smeared with grease, and surrounded by a flannel bandage: it is then placed in a wooden gutter, and secured there in a proper position; semifluid plaster is then poured around the limb, which is maintained in its position until the plaster is nearly hard. When quite solid, the gutter is removed, and the cast is scraped down, until its thickness does not exceed a quarter or a third of an inch.

No class of diseases has more severely taxed the mechanical ingenuity of medical men than that we are considering. In many cases, especially in young children, the hand of the surgeon is alone sufficient to restore to the foot its proper characters; but then when the hand is removed the deformity returns, and therefore, apparatuses of various kinds have been invented to maintain the foot in the position which has been given to it; these machines are varied with the particular deformity. Scarpa, Boyer, and others, have invented machines which have been in general use. By using such means, neglecting nothing which may relax the tissues, and strengthening those which are feeble, we may often in recent cases overcome the resistance of the retracted muscles, the ligaments, and even the plantar fasciæ, re-establish the bones in their proper position, and restore to the limb its vigour and its form. The promptitude of these results in the new-born infant, shows the necessity of early treatment, although in after years such results are sometimes obtained. Still, however well directed these means may be, they will often fail, and the fatigue and discomfort are always great; in consequence of these circumstances, another mode of treating these deformities is almost exclusively used in the present day.

Among the muscles which require elongation, in the treatment of club-foot, the extensors unquestionably hold the first place; their extension almost serves to cure pes equinus, and remedies the retraction of the heel, which constitutes the most formidable obstacle to the cure of varus; their tendon frequently forms an inflexible cord, when we attempt to reduce the foot in these two varieties, and if in the dead

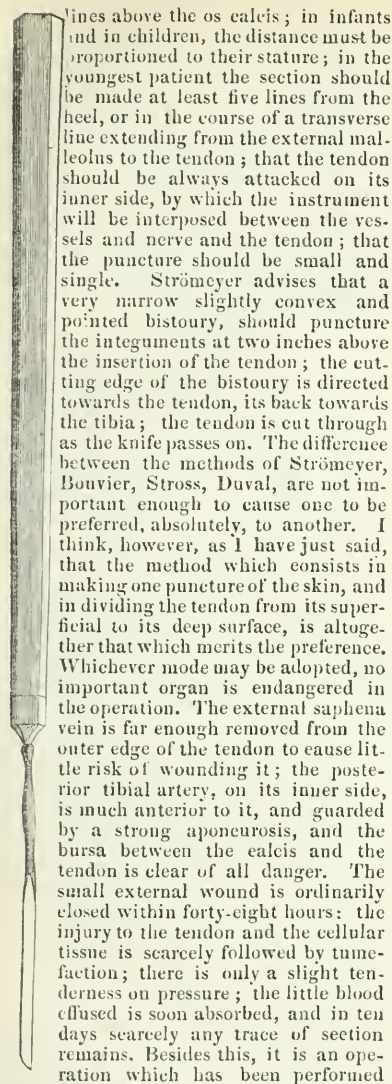

body it be divided, the main resistance ceases.

The section of the tendo-achillis is therefore an important element in the cure of these diseases; but it is not easy to say when it was first performed. In Limousin, and probably elsewhere, in the practice of the veterinary art, operations of this kind have been long performed: but for the cure of club-foot in the human subject, Thilenius, a surgeon residing at or near Frankfort, as far as I know was the first to describe it, (*Medic. und Chir. Bemerkungen*, 1789). His patient was a young woman of 17, who had suffered from her earliest infancy; she walked on the dorsum of the foot. On the 26th of March, 1784, the tendo achillis, *with the integument over it, was cut through*; the operator, M. Lorenz, maintained the foot in its new position; in six weeks the wound had cicatrized, and after a short time "she was able to walk like other people." Michaelis, of Marbourg, is the author of a memoir on the *partial section of tendons*, contained in the *Journal of Hufeland*, Nov. 1811: this operation he had practised in the course of 1809-10, in three cases of *pes equinus*, and one of *varus*: in the latter case, he cut the tendon of the *tibialis anticus*: the patients with *pes equinus* were from sixteen to eighteen years old. Sartorius, of the Duchy of Nassau, published in 1812, a case in which, in 1806, he cut the tendo-achillis in a boy of thirteen, who, in consequence of abscess of the back of the leg in his seventh year, had the tendon so contracted as to oblige him to walk on the dorsum of the foot: all means of extension failing, Sartorius, with a convex bistoury, made along the middle of the tendon an incision four inches long, opened its sheath, introduced the point of a bistoury under it, cut through it, when it retracted to the extent of an inch; he freed the tendon from the old cicatrizes of the abscess, forcibly drew the toes forward, which was accompanied by great pain and by a loud cracking, as all the toes were fractured: the patient was cured, but with tibio-tarsal ankylosis. So far, no attempt was made to lessen the wound of the integuments. Delpech, on the 9th of May, 1816, first endeavoured to leave the skin over this tendon intact. Spite of these successes, many years passed without recurrence to the operation: it was Strömeyer who next resorted to it, and with success; in the 39th vol. of *Rust's Magazine* are published the particulars of six cases in which he had modified the operation of Delpech. Instead of making a longitudinal wound along the tendons, he passed a very narrow bistoury through the integument, and under the tendon, which he cut, and the little wounds were well on the third day: instead of waiting

to make extension until the twenty-eighth day, he did it on the tenth in adults, in the fifth in children. Of those operations, the first was done Feb. 28, 1831, the last on the 11th of March, 1834; the youngest patient was seven, the oldest thirty-two; the disease was congenital in two, acquired in four: machines had been employed without success. In one case, the section of the tendo-achillis was preceded by that of the flexor of the great toe; in another case it was followed by section of the extensor tendon of the small toe: two were cured in a month, one in five weeks, one in six weeks, one in two months, one failed. How many cases he has since performed, I cannot tell: it would be well if he would publish the results of his extensive practice in this department of surgery: in 1838, I believe his sections of the tendo-achillis amounted to 60. In 1835, the operation was performed by Duval, in France, and immediately after by Bouvier, Guerin, and a multitude of others. In 1836, and again in 1837, the operation was performed in England by Mr. Whipple; Dr. Little followed him, and since that time it has been performed by most of our hospital surgeons. In 1836, Dieffenbach abandoned his system of treating club-foot by plaster of Paris; and in 1838, he had performed the section nearly two hundred times, and both himself and Duval had each performed the section of different tendons to the amount of 200 times.

The operation is extremely simple: the patient is placed upon his belly, the foot is flexed so as to make the tendon tense, when a narrow bistoury is passed on its flat through the integument, under its narrowest and most projecting part; when fairly under, the edge is turned towards the tendon, a sawing motion is impressed upon the instrument, and the tendon is cut through. Or, the patient being placed as before, a small puncture is made with the point of a lancet in the integument: through this puncture an instrument like the last, except that it has a blunt point, is passed, and the tendon cut as before. Or, with a sharp-pointed bistoury we puncture the integument, causing the instrument to glide on its flat between the tendon and the integument which covers it, and when the knife has fairly reached the opposite side of the tendon, its cutting edge is turned towards it, which by the same sawing motion is cut through, from its cutaneous to its deep surface; taking care that the point of the instrument does not press through the integument on the other side. Or, the same operation may be done with a blunt-pointed knife a line wide, such as the following.

Scoutetten's directions are, that the tendon should be divided in the adult, fifteen

lines above the os calcis; in infants and in children, the distance must be proportioned to their stature; in the youngest patient the section should be made at least five lines from the heel, or in the course of a transverse line extending from the external malleolus to the tendon; that the tendon should be always attacked on its inner side, by which the instrument will be interposed between the vessels and nerve and the tendon; that the puncture should be small and single. Strömeyer advises that a very narrow slightly convex and pointed bistoury, should puncture the integuments at two inches above the insertion of the tendon; the cutting edge of the bistoury is directed towards the tendon, its back towards the tibia; the tendon is cut through as the knife passes on. The difference between the methods of Strömeyer, Bouvier, Stross, Duval, are not important enough to cause one to be preferred, absolutely, to another. I think, however, as I have just said, that the method which consists in making one puncture of the skin, and in dividing the tendon from its superficial to its deep surface, is altogether that which merits the preference. Whichever mode may be adopted, no important organ is endangered in the operation. The external saphena vein is far enough removed from the outer edge of the tendon to cause little risk of wounding it; the posterior tibial artery, on its inner side, is much anterior to it, and guarded by a strong aponeurosis, and the bursa between the calcis and the tendon is clear of all danger. The small external wound is ordinarily closed within forty-eight hours: the injury to the tendon and the cellular tissue is scarcely followed by tumefaction; there is only a slight tenderness on pressure; the little blood effused is soon absorbed, and in ten days scarcely any trace of section remains. Besides this, it is an operation which has been performed

nearly or quite six hundred times, and it does not appear that it has destroyed the life of a single person: the only accidents recorded, and they are few, have been violent pain, abundant suppuration, and gangrenous eschars from improper pressure.

Delpsch, as well as several other operators, have thought it unwise to make extension until the two ends of the tendon are fairly united together by means of the newly secreted matter. This delay was thought necessary to ensure the union, as it

was feared that if extension were at once made, and the extremities kept far asunder, union might not take place: but the cases of Molinelli and that of Clement, where there was a space of two inches between the tendons, shew that this apprehension is groundless. Experiments on brute animals fully confirm this view of the case: and a case which occurred to Strömeyer shews the danger of allowing too much time to elapse before extension is made; the bond of union having become too unyielding to allow of stretching. We should not, however, like Sartorius, make violent extension at once, because of the pain and the chances of serious inflammatory action. I do not advocate excessive extension, because I know the interval between the two extremities of the tendon may be so great as to prevent the development of an available bond of union: but if on the one hand there be a limit to the reparatory powers of nature, and if on the other hand we should avoid the irritation of forced extension, there is a midway course to be followed; extension may be gradually made after forty-eight hours without any inconvenience.

As to the manner in which extension should be made, two things are to be borne in mind: the point of section should not be pressed upon, and there should be a means of very gradually extending. In *pes equinus*, the apparatus should not only flex the foot, but it should direct it inwards, to prevent the outward inclination which results from direct flexion; the foot should be flexed so as to exceed a right angle with the leg: for this purpose a few days are usually sufficient, unless there be resistance in the ligaments or the bones. In *varus*, the articulations of the two ranges of tarsal bones do not offer less resistance after than before the section of the tendon, so that longer employment of machines becomes indispensable to complete the cure.

LECTURES

ON THE

ALTERATIONS OF THE BLOOD.

By M. ANDRAL.

Disorders produced by Anemia in the functions of Nutrition.

Digestion.—The process of chymification in a healthy man is arrested by a blood-letting. Digestion is deranged in those affected with anemia; they are subject to nausea, vomiting, dyspepsia, &c. Exhala-

tious of gas are frequently met with in this affection, as well as in hysteria.

Circulation.—Syncope; palpitations of the heart, with acceleration of the strokes of the pulse; action of the heart irregular, tumultuous. *Bruit de diable* in the carotids is one of the best distinguishing characters of anemia, or chlorosis. This sound is not found in the heart. If the bellows sound exists in the heart, at the same time that it is heard in the carotids, it does not furnish us with a pathognomonic symptom of chlorosis, as, in this instance, it depends upon disease of the heart.

The capillary vessels are subject to passive congestions. In animals, destroyed by anemia, we find the conjunctiva of a bright red colour. Amaurosis, following anemia, is accompanied with injection of the conjunctiva, hæmorrhages of the capillary vessels, epistaxis. These hæmorrhages cannot be combated by antiphlogistic remedies.

Respiration.—Panting, dyspnœa. Auscultation sometimes gives us no results; at other times we discover pulmonary congestions, or œdema of the lungs, which are attended with a crepitus. Sanguineous congestions are produced in animals by anemia, or the loss of blood.

Secretions.—Urine pale, transparent, very watery.

Saliva.—The mouth often presents a dryness which might lead us to attribute it to an irritation of the stomach; but such is not the case.

Perspiration.—By bleeding a man, we make him perspire: in persons suffering from anemia, sweating is brought on by very slight causes. The exhalations from the serous surfaces are frequently increased, and dropsies are the consequence. Anasarca is often produced in children after losses of blood, or chronic diseases. During a famine, which prevailed in France, dropsy appeared in an epidemic form. Whenever the blood becomes impoverished, serous effusions show themselves; the blood being deteriorated, and the solids not receiving blood capable of repairing their losses, we should expect to find all the tissues of the body atrophied: but we do not find this to take place, except in the muscular system, whose nutrition is impaired, while that of the brain, liver, skin, &c. do not seem to suffer. The transparent cornea gives way in animals who have suffered great loss of blood. Anemia is favourable to the development of tubercles.

Anemia is chronic or acute. When spontaneous it is generally chronic; beginning with derangement of some of the functions either of digestion or the nervous system, with intermissions; the patient being one day better, another worse. Acute anemia

resembles a disease in progress. [Case: A. B. had headache; palpitations of heart; debility; chlorotic tint; vertigo; pulse 120; frequent faintings; appearance of fever towards night; with symptoms resembling a cerebral affection, for which this case was mistaken, and treated by blood-letting, during which syncope came on. When he was put upon large doses of iron, he was speedily cured.]

Anemia may end in health or death. Simple anemia may be fatal from the impoverishment of the blood, and death may take place during the debilitated state, attended by symptoms of nervous disorder, or pulmonary congestion.

2. Alterations of the Blood as to quality.

Alterations in its chemical or physical constitution may exist, which are inappreciable to all our means of research.

Some of the alterations of its physical qualities may be detected by the sight, &c. without the aid of instruments; others are only discoverable through the aid of the microscope.

First Section.—Physical alterations appreciable to our Senses.

Colour.—Its dark colour may become lighter, on account of its deficiency of colouring matter, as is seen in lymphatic and chlorotic persons. Venous blood may assume a redder tint, and be mistaken for arterial. After blood-letting, or large loss of blood, the last that flows is of a brighter hue. In different periods of disease this florid blood is seen, and it has been attributed to the arterial blood passing rapidly through the parenchyma, without undergoing any changes, or divesting itself of its principles for the purposes of nutrition, which latter function is found to be considerably impaired. Stevens attributes the changes in the blood to the different proportions in which the neutral salts, which it contains, may exist; Rossi, to the influence of electricity.

Influence of the section of the Nerves on the coloration of the Blood.—Several theories.

The venous blood may assume a darker hue, and become as black as ink. The venous blood has undergone this change by the introduction of a poison, such as the miasmata of typhus, &c. In some epidemics, according to Stevens, the blood presented that dark or black colour in persons in whom the epidemic disease had not as yet shown any of its symptoms; and, according to the same author, this blood, on exposure to the air, did not become red. In the cholera the blood was black; in scorbutic patients, the blood is found of a darker hue. The blood may become yellow, and

more especially its serum, without its containing any bile; animals stung by scorpions exhibit this appearance. If the blood becomes green by the addition of nitric acid, bile is present. The blood has sometimes presented a white or milky colour, or merely contained streaks of white, which were supposed to be derived from the presence of chyle or milk; but this whitish colour is produced by a greasy matter, described by Chevreul.

The buffy coat differs in colour from the crassamentum. It varies in thickness from one to nine lines, and is modified by the vessel which receives it. When thin it may be florid or greenish; when thick, white or yellowish. Its consistence does not depend upon its thickness. When soft on its surface, it frequently contains mucus; when well formed, the crassamentum on which it rests is very soft: may be partial or general, or cellular; as large as the crassamentum, or greater or less in size. Its shape may be flat, like the crassamentum, or it may be hollowed in the centre, and raised at the edges (cupped); may be perfect or imperfect. The appearance of the buffy coat, when perfect, is of importance; but, when imperfect, much value should not be attached to it, as it is met with in many dissimilar diseases. The buffy coat is composed of the fibrine, sometimes containing in its meshes serum and albumen; and on its surface is sometimes found a softish substance, which appears to be altered albumen.

The buffy coat, in its formation, is influenced by certain physical causes. Blood drawn from a vein will present a buffy coat; while the same, drawn, by cupping, from the capillary vessels, will not present a trace of it. According to the different forms of the vessels into which it is received it will be present or wanting; that drawn from a small orifice will not present it, and, if allowed to trickle down the arm, the same results will happen; though this rule does not hold good in all cases. If the bleeding be interrupted by a state of syncope, that which flows after the syncope will not be buffed. If the blood be well shaken it will prevent its buffing; and the same will happen if it be allowed to fall down from a height. If received into vessels which are large and flat, the buffy coat is with difficulty formed; whereas conical and narrow vessels favour greatly its formation.

Influence of diseases on the formation of the buffy coat.

If the character or disposition of the disease hinder or is unfavourable to its formation, we cannot promote it by any physical influences; and in those cases where

there is a disposition to its formation, it will make its appearance although opposed by the same influences.

The importance of the buffy coat has been admitted by some, and denied by others. Both these sects are in error. The buffy coat does not always imply the existence of an inflammatory state.

I have preserved notes of 1494 cases in which bleeding had been practised, the blood having been drawn from orifices of the ordinary size, and been received into vessels of the same size and shape. The following are the results:—

Perfect buffy coat...	in 613 of these cases.
Imperfect do.....	„ 183 „ „
No appearance of do. „	668 „ „

The buffy coat may be absent in all the different varieties of diseases. In its perfect form it is most frequently met with in the following cases:—

Acute articular rheum.	in 4-5ths of cases.
„ pneumonia.....	„ „ „
„ pleurisy	„ „ „
Pulmonary tubercles ..	„ „ „
Acute metro-peritonitis	„ „ „

In the first stage of pulmonary tuberculation the blood does not present this coat, but, as the stages of this disease are more advanced, it becomes more frequent; and, when caverns have been formed, the buffy coat is as often met with as in pneumonia, but its thickness is less. Next in order to these diseases comes erysipelas of the face, in which the buffy coat is found perfect in 3 5ths of the cases; imperfect in 1-5th; and absent in 1-5th. In angina and amygdalitis, it is found perfect in one-half of the cases only. Taking peritonitis and nephritis together, it is as constant in them as in pneumonia. In painter's colic, it occurs in one third of the cases; and in pulmonary emphysema and ophthalmia it is found in the same proportions.

Bronchitis, even when capillary, does not exhibit it in more than 1-4th of the cases, and the same proportion answers for gastro-enteritis and chronic rheumatism. In effusions into the pleura after fever, in intermittent fevers, organic affections of the heart, and cerebral congestions, it occurs in the proportion of 1-6th of the cases. In cerebral and uterine affections in 1-7th, and in lumbago in 1-10th of the cases. In typhus fever it is met with in 1-24th of the cases. In this latter affection the imperfect one is more frequent than the perfect one, and shows itself in 1-3rd of the cases. In the cholera the buffy coat was absent when advanced to the period of cyanosis. In hysteria, scia-

tica, pleurodynia, simple jaundice, it was either imperfect or absent; and not met with in neurosis, mental alienations, chorea, delirium tremens, saturnine epilepsy, facial neuralgia, simple or mercurial erythismus, scurvy, &c.

I have not many cases of scarlatina, measles, or small-pox, in which I have employed bleeding. In scarlatina I have never seen the blood with a perfect buffy coat, but frequently with an imperfect one; in measles very seldom; and in small pox I have found the buffy coat as the general rule, and I would place it in frequency after pneumonia, but my data are not sufficiently numerous, and the appearances differ according to the stages of the disease.

In speaking of small-pox, we must consider three circumstances; first, whether there be a complication of pneumonia or of pus in the blood; second, whether the eruption be distinct or confluent (all those cases in which the buffy coat was well developed, were of a confluent character); third, period of the disease: before the appearance of the eruption I found, as in typhus fever, no buffy coat; but I must say that I have bled but in a very small number of cases. After the appearance of the eruption, from the second to the fifth day, I have found a firm and thick buffy coat similar to that of acute rheumatism. At the period when the pustules become filled with pus, and when the fever of suppuration is established, the buffy coat still shewed itself, but becoming soft, thin, and imperfect, and covered with a kind of infiltrated mucus.

The buffy coat is imperfect or absent in epistaxis, bleorrhagia, cystitis, erythema, urticaria, and venereal buboes. I have never found it perfect in any of these diseases.

In chlorosis of a pure, simple, uncomplicated character, I have bled three times. In the first case I found the blood presenting a perfect buffy coat, thick, firm, consistent, with elevated edges, and, in this case, there was no fever—the crassamentum was small, with a large proportion of serum. In the second case, the blood was imperfectly buffed, and, in the third case, was not so at all. In another case of chlorosis, complicated with acute articular rheumatism, the blood was covered with a perfect coat.

It has been asserted that the blood drawn from a horse is always buffed and cupped; but that drawn from a healthy man is not so. De Haen and Boreski did not attach any importance to this coat, and denied its value. Authors often confound the part of the blood which becomes oxygenated with the buffy coat. Thoma-

sini attaches great importance to this appearance of the blood being buffed; and says it is to be met with in a circumscribed phlegmasia, or one of a general character, or in a phlogistic diathesis, such as is presented by a pregnant woman. He considers chlorosis as a phlogosis of the blood-vessels.

The blood may be buffed in all diseases; its value depends upon the proportion in which it is found in such and such diseases, and depends more upon a certain condition of the blood than upon any particular disease. This condition of the blood may be met with in different diseases, and may thus explain its appearances in such and such cases. I merely give this explanation, without attaching much value to it.

Influence of the febrile state upon the presence or absence of the buffy coat.

Fever alone will not produce it—witness typhus; however, we generally find fever accompanying its presence; for it does not exist in acute articular rheumatism unless fever be present. Plethora alone will not produce it. The constitution has no influence over its production. Does the complex phenomenon called inflammation, possess any influence over its formation? Those diseases which present the best-marked symptoms of inflammation are also those in which it is found most perfect. Its existence alone will not reveal the nature of the disease; and its presence does not furnish a reason for bleeding; for in phthisis it is always to be met with. In acute articular rheumatism, after twenty blood-lettings, it will still be found as long as the intensity of the disease lasts, and although the crassamentum of the blood becomes less.

The mechanism of the formation of the buffy coat is wrapped in the same mystery as the cause which produces it. Its formation is prevented, or with difficulty effected, when the blood coagulates too fast. If the blood does not coagulate, it will not be produced, and it is not necessary for its formation that the same condition of the blood should always exist. It may be formed under different conditions of the blood.

Theory of its formation.—The quantity of fibrine in the blood is increased, and, if the coagulation take place slowly, the fibrine becomes completely separated, and, its specific gravity being less than that of the globules, it floats on the top, forming there the buffy coat. M. Denis describes fibrine as a modification of albumen. The buffy coat is composed of a portion of the fibrine which separates from the globules. Why

and by what means produced? We can give no answer.

Alterations of the Odour of the Blood.

Morton describes a patient whose blood was stinking. Morgagni relates cases where it presented an acid odour. Stevens detects the yellow fever by the odour of the blood. I have never been able to discover any smell in the blood of small-pox or typhus patients. Poisonous substances might communicate their odour to the blood as they are carried along with it.

Alterations of the Taste of the Blood.

In the cholera the blood becomes insipid. The ancients said that, in Rachitis, it was acid.

Heat of the Blood.

In some diseases the temperature becomes elevated in several degrees, and it remains still to be seen whether the blood partakes in this elevation of temperature. It was asserted that, in the cholera, its heat fell three or four degrees, and, in the cold stages of intermittent fever, this lowering of the temperature had been noticed. I deny this fact; for I have seen, in the cold stage, the thermometer indicating a temperature equal to and even above the natural standard of a healthy man. In hysteria, where the nervous system is so much disturbed, we might expect to find the heat of the blood decreased. Morgagni relates a case of a young hysterical woman from whom the blood drawn was cold. I am not aware of any authenticated case, in medicine, in which the temperature of the blood was increased.

Electricity of the Blood.

According to Bellingheri, in what he calls inflammatory diseases, the blood drawn from a patient is deficient in electricity; and, according as the symptoms of inflammation are on the increase, the electricity of the blood decreases, and *vice versâ*. The electricity would be negative when the blood was flowing and was buffed, and would be less than in the healthy fluid. When the electricity was in great quantity, there would be no buffy coat; its electricity would be greater at the beginning than at the close of a bleeding; but on all those subjects science is still in its infancy.

Alterations in its Consistence.

Its consistence may increase to the extent either of becoming thicker or of becoming solid. It may be diminished, becoming very liquid, not forming any clot, when drawn from the body, or when found in the dead subject.

Augmentation of its Consistence.

The doctrine of Boerhaave was based upon the thickening of the blood, which, according to him, was such as to prevent its molecules from passing through the minute capillary vessels; thus producing a congestion, depending either upon this thickened condition or upon some change in other respects. In fevers, the blood becomes thickened by the escape of the liquid or watery parts, and by the increased temperature. Hoffman considered these obstructions produced by the thickened state of the blood, as giving rise to fever, and the conversion of the blood into pus. All those opinions are merely theoretic, being unsupported by proofs, and were upset by the solidists. At present those ideas are again brought forward; and Magendie has experimented on this subject. Substances which, mixed with the blood, thicken it—such as oil, grease, &c., were introduced into the veins of animals who died with either symptoms of pulmonary affections, or death was produced slowly by other causes. On examination he found congestions and extravasations of blood—engorgements resembling pneumonia in its first or second stages. Such occurrences may be explained by supposing these foreign substances incapable of passing through the lungs, and thus producing congestions. If charcoal be injected into the veins of an animal, he recovers from its effects, as the molecules of the charcoal, reduced to an impalpable power, are smaller and mingle with the blood without thickening it. The blood may thicken spontaneously, and, by analogy, we may believe that it may become so to such degree as will prevent its passage through the vessels, and congestions thus be formed: experience, however, does not prove this. In one case, by the aid of the microscope, was seen a portion of blood thickened, endeavouring to pass through, and stopped before the capillary vessels, until propelled through them by a violent contraction of the heart produced by the agitation of the animal. I am of opinion that a great number of inflammatory congestions may be accounted for by the thickened condition of the blood rendered thus incapable of passing through the smaller vessels; this opinion may, perhaps, one day be borne out by future researches.

Boerhaave thought that some kinds of food thickened the blood; and he is supported in this theory by some facts in physiology—as such a food producing a milky chyle, and another kind furnishing one of a different character. May these different chyles produce differences in the blood? We know not. Many diseases seem to be

cured by diluting the blood by means of drinks. Some skin diseases are thus removed. Water injected into the current of the blood separates itself, passing off either by absorption or through the kidneys. Water given to a sick person passes off by excretion, it being very difficult to dilute the blood, as this fluid, by a law of its own, endeavours to repel it: the blood is naturally viscous; its viscosity increases with the augmentation of its consistency. In the cholera its viscosity was increased, and the water of the serum diminished. The greater viscosity of the blood in inflammation has been attributed to the large quantity of albumen which it contains. The serum may become viscous, or its viscosity may diminish.

Coagulation of the blood during life-time.

We find clots in the heart, if we open the body fifteen hours after death, before putrefaction has commenced. In animals, we find them one hour after death; if we delay till twenty-four hours have elapsed, our chances of finding them are lessened, as the blood liquifies when putrefaction sets in. There are some cases in which the clots found after death have been formed during life-time—can we detect their formation in the living subject? The clots differ much from each other, and are found red, white, red externally, white internally, or white externally and red internally, or striated with red and white; these streaks have been taken for vessels, which is erroneous. Their consistence may be firm or soft, dry or infiltrated, and easily torn; their size may be large, occupying all the heart, and branching into the arteries and veins. The clots formed after death may contract firm adhesions with the walls of the heart internally. In the hearts of animals examined just after death, no clots are found; but in a few hours after we find them formed and adhering to the walls: around the clot is formed a pellicle resembling a membrane, and which may easily be mistaken for a false one, although it is merely a physical phenomenon, resembling the perfect buffy coat. Some clots are formed in the heart during life-time—are their characters similar to those formed after death? We can distinguish them by certain signs—but are those signs well marked? They are not; the physical peculiarities are not sure enough. If the clots do not present characters which serve to distinguish them from those which are found in almost all the hearts which we examine after death, I cannot place reliance upon the diagnosis which pretends to ascertain their presence during life. How can the blood so agitated as it is in the heart, coagulate during life-time?

The friability of these clots, and their grey colour, have been given as proofs of their being found during life: at the summit of the valves, when they are disorganized and rough, we find polypi which appear composed of several layers and presenting a degree of organization. The best signs of their formation during life are their being organised in their centres; but this we find very rarely.

I have injected the clots found in the heart, by the coronary arteries, and their being thus injected was considered as proving the existence of vessels in them; but I do not look upon it as such a certain sign. The existence of pus in their centre was advanced as another such proof; but has it been secreted there? Before we can admit it, we must allow the organization, the inflammation, and the power of secretion of the clot, which is far from being proved; for it may be formed by the endocardium in a state of disease, or carried into the heart with the blood, and at death has become separated from it, and afterwards surrounded or inclosed by it during its coagulation. I have never found pus in a clot which I could assure myself had been secreted there: clots may form during life in those cases which present some alteration of the lining membrane, a molecule of blood attaching itself to some part of its altered surface, and there shewing a tendency to conglomerate; this disposition may be increased by a condition of too great viscosity of the blood, and they have been found when the smoothness of the lining membrane has been altered.

The alteration which we now describe under the name of dissolution of the blood formerly was called putridity. It may exist in different degrees: in the one, the clot, although distinct from the serum, is so soft as to be readily broken down, and mixes freely with the serum under a slight touch of the finger; in the other the clot is absent, and a reddish liquid is found, with grumous masses floating about in the reddened serum. We must not confound the dissolution of the blood where the solid parts of that fluid remain uncoagulated, with that condition in which the coagulable principles of the blood are absent entirely or in part, producing a clot of small dimensions floating in a large proportion of serum: in the state of dissolution the solid parts of the blood merely form grumous masses mixed and confounded with the serum.

This condition of the blood may exist in different classes of cases: in one variety the cause which produces it is evident, as when a concentrated solution of sub-carbonate of soda was injected into the veins of an animal, by Magendie: the blood was

charged into a liquid of a reddish colour, containing portions of fibrine separated into grumous parcels. Does the blood become more alkaline where this state of dissolution exists? the following facts have been given as proofs. In blood of a scorbutic patient which was not coagulated, there existed a larger proportion of soda than natural. In a very severe case of typhus fever, Denys detected the presence of free ammonia and of an ammoniacal salt.

Bretonneau describes mercury as producing a dissolution, but this is not proved, and the same effect is caused, according to Grange, by the exhibition of resinous purgatives, cicuta, and laurel water. The sulphuric, nitric, and prussic acids, mixed with the blood in vessels, dissolve it; also some gases, as the sulphuretted hydrogen.

Influence of pus—It has been said to coagulate the blood which is found in an inflamed vein; it varies in its properties, being either acid or alkaline, sour or sweet, forming a bloody liquid or a thick one—and according to these different conditions it may produce corresponding effects: blood is not changed by the mixture of a laudable pus, but if mixed with serous pus, it is dissolved, and is prevented from coagulating. In some cases of resorption of pus, I have found the blood in a state of dissolution in the heart and bloodvessels; in other cases I have found clots in the heart, &c. Gaspard has dissolved the blood by injecting putrid matter into the veins: can this condition be produced by the introduction into the blood of imperceptible miasmata, and is it owing to their pressure that the blood in the plague and cholera is found dissolved? Do the pernicious intermittent fevers depend upon this altered condition of this fluid? The state of the blood in these latter diseases has not been ascertained.

Millman says, that in scurvy the blood is not changed; in the great majority of cases it is found dissolved. According to L'Inde, the blood is not changed in the first stage of this disease, but as it advances in its progress it becomes more and more altered until it becomes entirely changed into a reddish fluid. I am of opinion that miasmata are injurious by producing certain changes in the blood, which are not discoverable in the first days of the diseases.

Viruses.—In small-pox the blood has sometimes presented an imperfect buffy coat, and in the severe forms of it, it has been found dissolved. Is this owing to the presence of pus? The hydrophobic virus has been mentioned as producing the dissolution of it: I cannot give any opinion on this subject. Can it be produced by the food employed? I think that an in-

sufficiency of aliment, combined with bad air, may produce the scurvy: a humid atmosphere has been mentioned as a cause of the dissolution of the blood, which state, however, must be distinguished from its mere liquidity. The blood may exert influence over the nervous system, which may be differently excited by it, according to its various morbid conditions: this is a very serious question, and one very difficult to decide.

Dupuy, of the veterinary school of Alfort, has made experiments on this subject. After the section of the eighth pair of nerves, the blood has been uncoagulated: the function of hæmatose being by this section disordered, may it not account for this result? Meyer, on the other hand, did not find its coagulability impeded by this section. Authors assert that a violent commotion of the spinal marrow has produced this condition of dissolution: persons struck by lightning have presented the same appearance of dissolution. An animal tired to death has his blood in a dissolved state, purpura hæmorrhagica, a disease in which the blood has been found dissolved, may develop itself independent of any of those causes which we have as yet examined. I believe that in former times the dissolution of the blood, owing to various causes, was more common than at present, as may be seen by the description of the blood by the old authors, and the diseases which then prevailed.

Consideration of the causes which tended to produce this condition of the blood.

In the middle ages they were much more numerous, the habitations of men being more crowded together, the circulation of pure air more impeded, and the individuals more closely packed together; at the same time that the food was of a less wholesome quality, famine more frequent, the towns badly built with narrow streets never visited by the sun, the supply of water deficient, noxious, and impure in quality, &c. These sources of disease having been removed, we meet much more rarely in the present day those diseases which produce the dissolution of the blood.

The writings of the 15th, 16th, and 17th centuries, contain numbers of cases in which the blood was dissolved or coagulated very imperfectly, and many diseases characterized by this condition of the blood, such as scurvy, spontaneous gangrene, and purpura, are much rarer at present. The typhus fever which raged in Ireland some years ago, presented many of the features of those diseases which are described as belonging to the middle ages, and which are rarely met with at present, owing to the improved condition of the people:

their existence at the present day among the people of Ireland may be attributed to the events and poverty with which that unhappy people is afflicted, and which are not to be paralleled in any other part of Europe.

The state of dissolution of the blood produces symptoms resembling those of poisoning, and is very favourable to hæmorrhages: when the blood is merely in a liquid condition, dropsies but not hæmorrhages are produced: the secretions may be altered when the blood is dissolved, and tumefaction of the spleen is a very constant attendant in these cases. I do not think that the blood during life can pass into a state of putridity such as has been described by old authors.

We have so far described all those alterations of the blood which are recognisable by our senses, and we shall next describe those which are revealed to us by the microscope.

giving the proportion to the serum of 1.209. The serum resembled in appearance, coagulation by heat, acids, &c., that of the blood, but was less rich in albumen.

It was analysed in the same manner as the serum of the blood, by Le Canu's process, and gave the following results, which are compared below with Le Canu's analysis of the serum of the blood:—

	Fluid of Ascites.	Serum of Blood.
Fibrine.....	1.2092	
Albumen.....	52.0100	78. to 81.
Soluble matter consisting of saline and animal mat- ters.....	12.1.000	12.80—12.79
Water.....	934.6808	906.00—901.00
	1000.0000	996.80—994.79

NATURE OF THE FLUID IN ASCITES.

To the Editor of the Medical Gazette.

SIR,

IF the following chemico-physiological observations on the fluid drawn from the abdomen of a woman suffering from ascites, at present under my care, are thought worthy of insertion in your valuable journal, I shall feel obliged by the publication of them.

I am, sir,

Your obedient servant,

PHILIP B. AYRES,

Thame, Oxon,
April 14th, 1840.

CASE.—March 26th, 1840.—With the assistance of my friend, Mr. Lee, I performed the operation of paracentesis abdominis, drawing off about seventy ounces of a clear yellow fluid, which in a few minutes coagulated. The coagulum was at first nearly equal in bulk to the whole fluid, but rapidly decreasing in size, at the same time becoming firmer, and exuding a large proportion of yellowish serum. This unusual circumstance led me to convey the whole of the fluid to my residence, in order to subject it to chemical analysis. The coagulum was separated from the fluid, tied up in a linen cloth and washed, when it decreased to a very small bulk, and took on the usual appearance of fibrine: when dried, it weighed 38.5 gr.,

The apparent deficiency in Le Canu's analysis arises from the oily matters of the serum and some loss. I did not think it worth while to push my analysis so far as to ascertain the presence of the former in the fluid of ascites.

By comparing the relative quantities of albumen and water in the fluid of ascites, and that of the serum of blood, it will be found that the deficiency of albumen in the former is made up by water, and that the additional quantity of water almost exactly corresponds with the excess of albumen in the serum of the blood.

The proportion of fibrine in this fluid is found on comparison with Le Canu's analysis to be smaller than that of the blood; in the former it was 1.2092, whereas in the latter it amounted to, from 2.100 to 3.565.

These observations shew that, in point of fact, the fluid in this case was no other than the *liquor sanguinis* of Dr. Babington, (vide Turner's Chemistry.) in a diluted state, and as the abdominal cavity had been distended with fluid for several months, it is evident that the *liquor sanguinis*, or serum holding fibrine in solution, may exist without deposition of fibrine, during a considerable time out of the current of the circulation, while surrounded by tissues endowed with vitality; but as soon as the contact with those tissues is withdrawn, the fibrine immediately separates.

I have never before met with a case

of this kind in the course of either my practice or reading, nor does it appear that such a case is on record, as I find that Dr. Copland, than whom few men have been more extensive readers, in his *Admirable Dictionary*, states that, "The characters of the effused fluid have been remarkably overlooked. They vary extremely, but they generally have some reference to the state of vascular action in the seat of the effusion. When this has been considerable, the fluid is more or less whey-like and turbid, or it contains pieces of albuminous (fibrinous?) matter, or flocculi or fragments of filamentous lymph (fibrine)." And further on, "In some instances, and particularly in ascites or ovarian dropsy, the fluid collected after repeated tapping, often assumes diversified appearances. It has been remarked of a yellowish, greenish-yellow, or greenish colour, or brownish, or even nearly black, by Morgagni, Littre, and others. It has likewise presented puriform, viscid, gelatinous, milky or chylous characters, according to Willis, Morton, Becker, Coste, and Pochaska." And "the puriform and viscid or jelly-like effusion is probably caused by sub-acute or chronic inflammation." In his account of the varying appearances of the fluid of dropsies, we have no notice of such an occurrence as coagulation, and it is probable that had he met with it in the course of his reading, it would have appeared in his invaluable work.

Dr. Marcet, who paid particular attention to the chemical constitution of animal fluids, found that the fluid of dropsies was very variable as to the proportion of its constituents; and that these varied according to the situation of the dropsy, being least in hydrocephalus, and greatest in hydrocele; the allowance being 2.2 in 1000 in the former, but 71.5 in the latter. The proportion of saline matter was least in hydrops pericardii, but greatest in spina bifida, being 7.5 in the former, but 9.2 in the latter.

In an analysis of the fluid of ascites, by Marcet, the albumen amounted to only 22.6 in 1000; another specimen analysed by Bostock, contained 42.5; while in both these specimens the amount of saline matter was nearly the same. Berzelius states, but without giving any authority, that it has been found almost as concentrated as the common

serum of the blood, and containing seven per cent. of albumen.

The only notice I have seen of the effusion of serum holding fibrine in solution, is at page 899 of the fourth edition of "Turner's Elements of Chemistry," where he says, "The *coagulable* lymph of surgeons which is thrown out on cut surfaces, appears to be the liquor sanguinis, and this fluid is not unfrequently exhaled in dropsies when the fibrine constitutes either a gelatinous deposit, or appears as white flakes floating in the serous fluid." And Berzelius, "Traité de Chimie," vol. 7, p. 108, where the following passage occurs:—"Dans les états morbides inflammatoires, auxquels les membranes sereuses sont exposées, le liquide sécrété devient quelquefois chargé de fibrine. Celle-ci ne tarde pas à se coaguler, et forme sur la membrane séreuse une nouvelle ou fausse membrane composée de fibrine, et qui ordinairement rend adhérentes les unes aux autres les parties entre lesquelles a lieu l'épanchement que la produit."

In both these extracts, it is evident that the *liquor sanguinis* was not seen as a clear fluid holding in solution a quantity of fibrine; but the fact of the effusion of the liquor sanguinis, is founded on *ex post facto* reasoning. Because a serous fluid, holding in suspension flakes of fibrine, was found in the serous cavity, therefore the liquor sanguinis was effused. I do not object to the reasoning, but it shews that that fluid had not been observed in its pristine state as the fluid of dropsy.

This case proves, 1.—That the *liquor sanguinis* is effused in certain dropsies.

2.—That it may remain for some time in a liquid state, when out of the current of the circulation, while surrounded by parts endowed with vitality.

3.—That it coagulates in consequence of the withdrawal of the vitality communicated by the living tissues by which it was surrounded.

4.—That the fibrine is *not* held in solution or suspension by the motion in the vessels.

5.—That the *liquor sanguinis* is effused in a liquid state in serous inflammations, but owing to some unknown cause it immediately coagulates.

6.—That coagulable lymph is the liquor sanguinis, the fibrine of which agglutinates wounds by its coagulation.

TAPPING IN CONGENITAL HYDROCEPHALUS.

To the Editor of the Medical Gazette.

SIR,

THE valuable paper of Dr. Conquest on tapping the head in cases of hydrocephalus, gave me much pleasure; and I determined to avail myself of every opportunity of testing the value of such a plan. The only case in which I could venture to try it was the following, the particulars of which I beg to submit to the profession.

I was summoned to attend Mrs. C—— in her third pregnancy; labour was tedious, notwithstanding she had very strong pains. I was surprised at this, as her pelvis was exceedingly well formed, and her previous labour was easy and pretty quick. As the labour advanced, I was surprised at the size of the head, and its doughy, yielding feel, and after several hours of laborious labour, she gave birth to a well-formed, full-sized foetus, with a head nearly double the ordinary size. The child at first appeared dead, but by using the ordinary means, in a few minutes cried lustily. There was no difficulty in deciding that the largeness of the head arose from the presence of fluid. The pupils were natural, the functions of digestion, secretion of urine, respiration, were correctly performed, and it sucked freely, and except the inconvenience which it occasionally suffered from movement, owing to the enormous weight of the head, it seemed tranquil and comfortable. It was deemed advisable to leave the infant to nature for a little time: at the expiration of ten days the head had become sensibly hotter, bowels disordered, and the child had become anxious and fretful. Cold lotions and cretaceous medicines were administered to little purpose; I therefore proposed to the parents that the fluid should be drawn off, and, with their consent, I introduced a small trochar into the head, at the side of the fontanelle in the line of the coronal suture, and drew off about ten ounces of straw-coloured fluid: as the fluid escaped, the bones collapsed, the parietals overlapping each other, and the occipital the posterior edges of the parietals. Adhesive strips and a bandage were applied: the child cried very much during the operation: the head was reduced to the ordinary size. For several hours after

the operation the child was cold, skin clammy, and serious apprehensions were entertained for its life. Next day, however, it had obviously much improved, and with some little medicines in a few days seemed very much benefitted. It was obvious, however, after the first week, that the fluid was again accumulating. At the end of three weeks the head had acquired its original size, and I again tapped: the fluid this time amounted to about eight ounces. The improvement after this operation was not near so marked; the child seemed to suffer considerably for days after, and the fluid began to accumulate more early and more rapidly than on the previous occasion, and at the expiration of a fortnight was as large as when I last operated. The parents became disheartened, and refused to allow another operation. After this, the head continued to enlarge; the child suffered considerably, and it became necessary to administer opiates to get any relief at all. When about three months old, it had a most severe attack of crusta lactea, which at first it was hoped might prove beneficial, and therefore little was done to relieve it, until the itching became so tormenting that I was obliged to prescribe for it. It would be waste of time to narrate all the particulars which week after week presented themselves. The child suffered so much, that the mother was frequently obliged to have recourse to opiates, until at last the dose of this medicine (tinct. opii) had arrived at the fearful dose of a teaspoonful and a half for this infant. During the last month the child wasted to the greatest extent, refused the breast, and all other nutriment, and after some slight convulsive efforts, died 6th March, 1840, aged six months and a half.

Next day I examined the head. The measurements were

	Inches.
Circumference of the head . . .	20½
From tip of one ear to the same point of the other ear . . .	13
From meatus audit. externus to the middle of the forehead . . .	6
From the root of the nose to the occipital protuberance . . .	17

The water was now drawn off, and amounted to seventy ounces, or three pints and a half; it was clear, light straw colour, and there was only one small flake of coagulated lymph in the entire. It was not coagulated by heat. The fluid, as it escaped, left the bones of

the head standing in strange array, the process of ossification having considerably extended, so that when the fluid had entirely escaped, they overlapped very much. The fluid was contained under the dura mater, and rested almost entirely upon the cerebrum, for though there was a considerable quantity under the tentorium, by far the largest portion was above it. The brain itself, from the continual pressure, was flattened out, and spread over the interior of this great cavity, in some places not thicker than a shilling. It was impossible to make out any of the sinuses, nor the parts which are described as in them: the pressure seemed to have obliterated all these distinctive parts of the organ. The nerves could be readily distinguished, except the olfactory; the brain was about the ordinary firmness of that period; the arachnoid was injected generally, and the dura mater was pale, and washed-like.

It is not my intention to offer any observations on the case: our object at present ought, I apprehend, to be to collect facts. I would just remark that some time back I had the pleasure of meeting Dr. Conquest, when I mentioned the case. He said his experience was unfavourable to the operation in congenital hydrocephalus.

Should any other opportunities occur of testing the soundness of the remedy in my practice, it is my intention to avail myself of them, and then to contribute my mite to the profession, on this important department of pathology.—I am, sir,

Your obedient servant,
JOHN ARMSTRONG.

Gravesend, April 18, 1840.

EXTRAORDINARY CASE OF CONSTIPATION.

To the Editor of the Medical Gazette.

SIR,

I SEND you the following case:—

March 22nd, 1835, I was called to Miss Catherine T—, the daughter of a farmer, 18 years of age; she was low in stature, florid complexion, robust, and corpulent, and had hitherto enjoyed good health, with catamenia regular. She was complaining of pain in her head, back, and chest; bowels confined, and every thing she took into her stomach was rejected immediately. I found she

had, the previous week, while menstruating, exposed herself to cold, which suddenly checked that discharge. Opium, with common saline medicines, allayed the irritability of stomach, but her bowels were not acted on for two days, when she parted with a great quantity of hard feces, and was to all appearance released from every urgent symptom.

I did not see her after this for two or three weeks, when her mother called and stated that her daughter's bowels continued very obstinate; that she had given her purgatives of different kinds, none of which produced any effect, although she did not reject any of them, but everything in the form of food was thrown up in twelve or fifteen minutes, without any mixture of bile, or any change from the state in which it was given. Upon visiting her I found her thinner, but not suffering so much from constitutional derangement as I should have expected, when I was informed she had not had her bowels opened for fourteen days. I gave her some few purgative medicines, and took some blood from her, but these having no effect on the bowels, and the sickness being worse, I had recourse to enemata, which brought away immense quantities of scybala; these were continued for some time daily until they were returned unchanged. She now took a few other medicines, but the stomach became so very irritable, and the sickness so extremely distressing, they were altogether discontinued. Blisters were now applied to the epigastric region, without producing any change. She continued in this state, eating as usual—rejecting her food in about fifteen minutes; her bowels never open, and no appearance of catamenia, and could not be prevailed on to try any other means until the month of October, when I prevailed on her friends to see a physician in consultation, who considered the case so extraordinary, that he recommended her to discontinue the use of medicines altogether, and only use a stimulating embrocation to the chest and abdomen; to use injections two or three times a week, and once a fortnight apply six leeches to the anus. This plan was continued some time without doing any good, the injections generally returning in the same state as given.

Every remedy was now given up by herself and friends as useless, and from that time she has continued in the same

state, and although she has gradually lost her flesh, she still assists in the duties of the house, and seldom or ever retires to bed before the rest of the family.

I should have remarked she has occasionally, at intervals perhaps of two or three months, when more violently sick than usual, parted per anum with about a table spoonful of slimy matter smelling slightly of fæces. She is now so very much reduced that there is no difficulty in making an examination of the contents of the abdomen: the parts are flat, and the abdomen empty; she can bear the hand being heavily pressed over every part of it, except about that portion of the hypogastric region over the pylorus, where an enlargement about the size of a small walnut is very evident, and when that part is only gently touched, she describes the sensation "as if something was about to be forced from her stomach into her throat."

Not having made notes of the case from the beginning prevents me being so particular on some points as I could have wished; but taking the case on the whole—that a person shall be five years without an evacuation from the bowels, without menstrual discharge, and incapable of retaining her food more than ten or fifteen minutes, and still be able to go about the duties of a farm house,—it is so extraordinary, that I thought you would not deem it unworthy a place in your valuable journal.—I remain, sir,

Your obedient servant,

GEORGE OLIVER.

Newton-on-Trent, near Newark,
April 16, 1840.

P.S. I should be glad to supply any further information if required.

NERVES OF THE UPPER EXTREMITY.

To the Editor of the Medical Gazette.

SIR,

ONE of my students this forenoon was dissecting the superior extremity, and asked me to point out to him the nerve of Wirsberg, as it was not, he said, mentioned in his book. On looking at his book, Quain's Anatomy, it is not so much as mentioned; and, in Harrison's Dublin Dissector, the best manual with which I am acquainted, and which I recommend to all my students for their companion at the dissecting table, it is not described, but the name of the

nerve of Wirsberg is applied to the two, or sometimes three branches, which come off from the second, third, and fourth intercostal nerves, at the greatest lateral projection of the ribs, and generally lose themselves on the skin which shuts up the base of the axilla. These are more properly called the intercosto-humeral nerves.

The nerve in question is described by Sir C. Bell, in the second vol. of his Anatomy, p. 574—a book which is not in general very minute in its details, though it has many other valuable qualities. It is there called the nerve of Wirsberg. I forget who gave it the designation of the *cutaneus minor*, by which I am accustomed to demonstrate it.

In the subject looked at to-day, it arises from the lower of the three divisions of the brachial plexus—from the same root as the internal cutaneus and ulnar, internal to which last it lies. It runs down along the inner side of the basilic vein beneath the fascia, perforates it about a hand's-breadth above the elbow, and divides into two branches, one of which runs in front of the inner condyle, and the other, rather larger, behind it, and both lose themselves in the skin a little below the elbow. In some subjects I have seen its origin very small from the axillary plexus; and then it derived an additional root from some of the intercosto-humeral nerves.

When writing, at any rate, I may add a remark on a set of muscles said to have been discovered by some German, and noticed in one of the numbers of the GAZETTE last winter, under the name of *Rotatores dorsi*. I must confess that, when I read it, I disbelieved their existence, from what I knew of the structure of the dorsal spine, where rotation is impossible, on account of the form of the articulating processes of the vertebræ, and on account of the ribs being superadded. Nothing, however, is too absurd for a German periodical.

If the *multifidus spinæ* be dissected away with care, its deepest fibres will be seen arising from the lower edge of the arch of one vertebra near its spinous process, and passing obliquely down to be inserted into the root of the transverse process of the one below; but these have no more claim to be considered distinct muscles than the outer fibres of the lower fasciculi of the same muscles have, which pass over one, or

sometimes two transverse processes, before being inserted.—I am, sir,

Your obedient servant,
JAMES DOUGLAS,
Lecturer on Anatomy.

Glasgow, 17th Apr'l, 1840.

PUNCTURE OF THE BRACHIAL ARTERY.

To the Editor of the Medical Gazette.

SIR,

MR. PHILLIPS'S lecture on varicose aneurism has brought to my remembrance a case in which puncture of the brachial artery was successfully treated by compression.

The patient was bled for some affection of the chest, and the brachial artery unfortunately wounded: the hæmorrhage was profuse. A compress was immediately applied to the wound, and the arm bandaged from the hand to the shoulder. The limb was kept in a state of rest for a fortnight; no bad symptoms occurred, and, at the end of this time, the bandage and compress were removed. Pulsation was found in the artery at the point of puncture, but there was no aneurism, and no further treatment was necessary.

The patient died at the end of five weeks after the accident, from the chest affection, for which he had been bled, thus giving an opportunity not often met with of examining the state of the parts. There was a slight effusion of serum about the neighbourhood of the puncture; a cicatrix in the posterior wall of the vein; condensation of the cellular structure between the artery and vein, giving it a thickened sensation to the fingers when squeezed between them; an orifice in the anterior wall of the artery about a line in diameter, filled with a plug of lymph apparently becoming organized, and which looked like a small coagulum: the edges of the orifice were everted, as if they had been driven out by the stream of blood rushing from the artery: both the artery and vein were as pervious as in the natural state.

It would seem, from this case, that the process by which a punctured artery is healed is not always by the formation of a coagulum *external* to the artery, and the effusion of coagulating lymph between the edges of the wounds; for

though, no doubt, extravasation did take place in this case into the cellular substance, causing the thickening perceptible between the artery and vein, still this only acted immediately by allowing the formation of a plug in the arterial wound. This plug had not the appearance of coagulating lymph effused between the edges of the wound, for they were everted, but was evidently a coagulum formed by the stream of blood which had caused the eversion.

In disease of the heart I have seen coagula adhering to the internal serous coat, and becoming organized, and so, no doubt, might this plug, and thus would the obliteration of the puncture have been effected if the patient had lived long enough.

This case also shows that an operation is by no means always necessary when this accident occurs. Two other cases have come to my knowledge where the compress and bandage were successful; but the use of the bandage is necessary, rest being enjoined. The mere employment of compression at or above the wound can only be justifiable as a temporary expedient, and then it exposes the patient to great suffering, and, if persisted in with any view of cure, may lead to a fatal result. This happened in a case of puncture of the artery from bleeding, the limb becoming frightfully œdematous, and such a state of exhaustion taking place as not to allow of an operation.

In a case which came under my own care, of a scythe-wound of the posterior tibial artery, the cure had been attempted by compression at and above the wound. The wound was sloughy, and the patient so exhausted by the repeated attacks of hæmorrhage, that a few days more must have terminated his life. I tied the artery at and above the wound, and eventually the case did well.

If, then, compression be tried—and it really appears to me that, in wounds of the brachial artery from bleeding, we are bound to try it before resorting to an operation—the bandaging of the limb seems essential as diminishing the arterial, and, if properly used, as assisting the venous circulation, and thus preventing œdema.—I am sir,

Your obedient servant,
JOHN BARRETT.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."
 CICERO.

ON EXCLUSIVE SYSTEMS IN
MEDICINE.

THE medical student is often warned against those sturdy system-mongers who would confine nature within the iron walls of their narrow theories, and who, consequently, overlook or distort the most palpable facts, when they do not happen to square with their preconceived fancies: yet, often as this warning has been given, it still needs frequent repetition. An exclusive system offers, more or less, the temptation of 'physic made easy.' Almost all diseases are to be reduced to varieties of some single malady, thus saving the trouble of diagnosis; and all remedies are to be superseded by bleeding, or quinine, or *diète* and *eau gommée*, which much diminishes the difficulty of prescribing. Not many years, for example, have passed away since the antiphlogistic system reached its acmé in this country; when bleeding and mercury, separate or combined, were supposed to be exquisitely adapted for the majority of cases. Bleeding is the established remedy for inflammation, and it does not require much ingenuity in a practitioner to find acute or sub-acute inflammation, or perhaps some lighter shade than either of these, lurking under every train of symptoms. The lancet, it has been said, has destroyed more than the sword: perhaps this is an exaggeration, but certainly many practitioners, A. D. 1820, were determined to try the experiment. When we read such cases as those recorded by Dr. Marshall Hall, where patients were bled to cure the symptoms

caused by venesection, and where a woman was bled, "as if by infatuation," a few hours before she expired from exhaustion, we think of Moliere and Le Sage, and confess that the utmost extravagance of fiction is not a caricature. The variety of the antiphlogistic system, propounded by Broussais, is familiar (in name, at least) to most of our readers. An inflammation of the mucous membrane lining the stomach and bowels is supposed to be at the bottom of almost every disease; and leeches, with cold water and the lowest diet, to be the appropriate remedies. At the same time that the antiphlogistic theory was so fashionable, and the practice so destructive, the hepatic sect flourished. Those who are approaching that age, when even the unlettered layman begins to be a physician in his own case, may recollect how popular a disease hepatitis formerly was; the phrases, "Doctor, I think I have a touch of the liver-complaint," or, more simply, "of the liver," are still ringing in their ears. It was then that, to use the expression of Dr. Abercrombie, patients were subjected to "long and ruinous courses of mercury" for imaginary disease of the liver. Yet then, as now, diseases of the liver were far from being very common; but, alas! we are obliged to look at Nature through the spectacles of books, and the glasses are too often tinted *!

* "On surveying the returns of affections of the liver, we have certainly been impressed with the scantiness of their contributions to the general mortality of most of the districts where their influence has been traced; and it will occur to the reader either that such affections figure much too highly, in the opinion and language of certain medical men in this country, or that they are the most curable of human maladies. These returns, however, disprove the latter branch of the alternative; for we find the proportion of deaths to the number treated by no means insignificant. The fact appears to be, that, throughout the western hemisphere, diseases of the liver are very rare in comparison of those of the lungs, and of the stomach and bowels; and though, in some localities, they are more frequent than diseases of the brain, they contribute much less than these do to the amount of mortality."—*Br. and For. Med. Rev.* Jan. 1840, in a review of Major Tulloch's Statistical Report, &c. of the sickness of the British Troops.

It is hardly necessary to mention other species of this professional amaurosis, where a writer can see little more than one sort of disease; but *that* one he sees in clouds, and "hears it in the wind." Addison, in one of his papers on false wit, tells us of certain scribblers called the *lipogrammatists*, or letter-droppers, who would compose a poem, throughout the whole of which some one letter was studiously omitted*. The authors of false medicine, however, go much farther than this, and, instead of being satisfied with excluding one letter, must needs exclude all but one. An amusing essay, by one of these zealous exclusionists, is now lying before us†.

Dr. Dickson's glasses are far, indeed, from achromatic; they give a singular tinge to every object around him; and he can see nothing but intermittent fever. He is able to see that what he strangely calls "the spasmodic notions of Hoffman and Cullen—the putrid doctrines of Pringle," are no longer in vogue; but he cannot see that his own notions will never get into it; that his own doctrines will never be ripe enough to be putrid! If, however, the theories of these great physicians no longer reign in the schools, the practice which they founded on them still influences ours; and the meanest village leech practises very differently from what he would have done had Pringle and Cullen never lived. Few now read Boerhaave or Hoffman: many do not even read Sydenham (more shame for them!) but the practice of these great masters is as universally diffused as the gentle gale of the spring, though they who breathe it do not know whence it comes!

Intermission, says the subvertor of the received practice of physic, is the charac-

teristic both of health and disease. Life, say Shakspeare and Dr. Dickson, is a fitful fever. Sleep and watchfulness, hunger and satiety, succeed each other at regular intervals. We might add, that the pulse does not beat with the same frequency in the morning and evening; and physiologists tell us that we are taller when we rise than when we go to bed. "His lungs now inspire air—now expel it; his heart successively dilates and contracts; his blood brightens in one set of vessels only again to darken in another."—(*Dickson*, p. 3.)

In disease this transmission is equally marked; the symptoms never remain at the same height for a continuance, but alternately swell and sink; and, therefore, says the subvertor, all diseases are essentially agues, and require the same treatment.

When a disease, though not called ague, is distinctly periodical, it confessedly should be treated like an ague; "Why, then, deny that the same disease, under other circumstances, partakes of that variety of ague misnamed *continued fever*?"

But granting that pleurisy does partake of the nature of continued fever, is continued fever commonly benefited by quinine or arsenic? Dr. Dickson says "Yes!" Experience says "No!" and we are content to side with the latter. The subvertor, who is not deficient in ingenuity, relies much on the fact that continued fevers are not in reality perfectly continuous, but have their remissions and exacerbations. To attest this he quotes Drs. Thomson and Shearman, and might have quoted Cullen*.

* "I would say, therefore, that there is no such fever as the schools have agreed to call a 'continent'; but that every fever which runs out to more days than one, is formed of repeated paroxysms, recurring in the course of twenty-four hours, or truly consists of diurnal exacerbations. * * * To all this I would add, if it can have any weight, that in the course of nearly forty years' pretty extensive practice, I have never observed what I could call a continent fever, but could always discern, by

* Spectator, No. 59.

† The Unity of Disease Analytically and Synthetically proved, with Facts and Cases subversive of the received Practice of Physic. By Samuel Dickson, M.D., &c. London, Edinburgh, and Dublin, 1838.

The simple answer to this is, that although, in strict logic, *majus et minus non variant speciem*, in physic, as in common life, we are obliged to admit the essential difference of things which differ only in degree. If the servant of the most zealous logician were to bring him for breakfast only the one-hundredth part of his usual fare, he would hardly be persuaded that this was his regular meal in a slighter form, but would consider it as no breakfast at all; and thus, when the remission of symptoms is trifling, it may be safely neglected, but cannot be safely made the chief indication of treatment. On this point experience is our sure guide. The tonic treatment of fevers, including the use of bark, was formerly common enough, and was discontinued only because its results were unsatisfactory. There are exceptions, unquestionably; but the rule seems to us well made out.

The truth is, that the pendulum of medical practice, not only in fevers, but generally, is constantly vibrating between the antiphlogistic and the tonic systems. It was long on the former side of the arc, and is, perhaps, still too much inclined that way; but vast efforts have been made of late years to drag it to the tonic side; and Dr. Dickson's lively, but unsound, treatise is a mere indication of changing sentiments in the medical republic—a straw that shows which way the wind blows. If, indeed, it were a solid reason for employing antiperiodic remedies in every case, that all diseases have remissions, the antiphlogistic physicians would have been almost equally justified in their use of the lancet, as nearly every case shows some slight mark of inflammation. The hepatic doctors, too, would allege in their defence, that almost every patient, when sufficiently pushed about the

right side, shows some token of uneasiness.

Dr. Dickson has reduced the practice of physic to such extreme simplicity, and has made diagnosis so unnecessary, that we cannot be surprised if so troublesome a method of arriving at knowledge as the stethoscope, meets with no favour at his hands. In good truth, "the wooden oracle," as Dr. Dickson calls it, becomes merely an ugly toy, as soon as we know that every distemper is at bottom intermittent fever. Why bore the patient with the ominous tube, when every question in the catechism of disease requires the same answer? What is empyema? Intermittent fever. What is emphysema? Intermittent fever: and so on to the end of the chapter.

If, indeed, the stethoscope were used to the exclusion of all other methods of investigation—if the practitioner thought much of ascertaining the disease, and little of relieving it—we should be inclined to cry out against it as lustily as Dr. Dickson; for a practitioner who can adopt only one mode of investigation, like him who can see only one disease, is not a very useful member of the profession; his performances are like a tune played on one string, which even Paganini could not long make supportable. But when the stethoscope is used to assist other inquiries, and not to supersede them, it is so valuable an ally, that had the present age witnessed no other improvement in physic, it would of itself stamp it as an era of advance.

Celsus has said that the pulse is most deceitful, and so it is, singly; yet we all feel the pulse—Dr. Dickson, perhaps, not excepted. Boerhaave observes, with his usual discrimination, that chemistry is an excellent hand-maid to medicine, but a very bad mistress; yet as we do not reject chemistry, let us also retain the stethoscope.

As for remedies, Dr. Dickson's list of them is pretty long; he is not an ex-

attentive observation, more or less of exacerbation and remission."—*Cullen's Works*, vol. i. pp. 511 and 512, ed. 1827.

SOCIETY FOR RELIEF

OF

WIDOWS AND ORPHANS OF
MEDICAL MEN

IN LONDON AND ITS VICINITY.

clusionist here. Baths, cold affusion, mineral waters, exercise and change of air, plasters, bandages, emetics, purgatives, mercury, bark, quinine, prussic acid, tar, creosote, opium, morphia, alcohol, musk, valerian, camphor, asafoetida, sulphur, guaiac, turpentine, copaiba, eubeb, cantharides, squill, digitalis, iodine, arsenic, and iron, all figure in the catalogue. So that if a cough under the new system is never to appear, excepting under the name of intermittent fever, it is, nevertheless, permitted to keep company with squill: like a new-married woman who still associates with her school-fellows. Or, as Dr. Dickson expresses it, "these agents have all more or less control over intermittent fever: they exert, moreover, a special influence over particular organs, and consequently are capable of curing, causing, or aggravating diseases attended with certain local peculiarities."

On the whole, Dr. Dickson's treatise, though by no means void of pith and point, is far more amusing than instructive. He has pointed out, indeed, some of the misdeeds of the antiphlogistic system, or rather of the antiphlogistic mania; and he has given a number of instances where well-marked intermission accompanied a great variety of diseases; but he has entirely failed to show that the slight remissions of continued fever, or other maladies, place them in the same class, therapeutically, as intermittent fever. This could only be done by giving a long series of cases treated on this plan, with the results; but this the subvertor of the received practice of physic has not done. To the student we would say, do not examine each new patient with a predetermination to find disease in the liver, the heart, or the kidneys; nor with the fixed belief that calomel or that quinine is a panacea; but judge each case on its own merits, and aspire to the glory of being an eclectic physician!

MEDICAL men are said to give more time than money in charity; lawyers more money than time. Perhaps the two gifts are never more agreeably and beneficially bestowed than at the annual dinners of this excellent society, one of which took place last Saturday at the Freemasons' Tavern, and was attended by about fifty members and others. A numerous list of stewards, more than half of whom had volunteered their services for the second or third time, and most of whom discharged actively and zealously the duties of their office, secured those appliances without which physiologists well know that even the most fervent charity is apt either to neglect its work, or to do it in a slovenly and ungraceful manner. In proposing the health of these gentlemen, Sir Charles Clarke well remarked, "that he considered their office to be one of great importance, for the existence of stewards was necessary to the existence of a dinner; and how much good is done by the dinner was proved by the list of donations which the treasurer annually receives and announces on that occasion, the contributions being usually very large in proportion to the numbers assembled." The usual loyal and patriotic toasts were followed by "The Royal Colleges of Physicians and Surgeons, and the Society of Apothecaries;" in acknowledging the last of which Dr. Merriman happily remarked, "that whatever contribution that body might have made to public or professional improvement, there was one example which might be suggested for the imitation of the two Royal Colleges; viz., the giving an annual benefaction to the funds of this society. A little business, but not enough either in quantity or quality to interrupt the most laborious digestion, was done, by the distribution of the annual statement in an amended form, calculated to shew more clearly the existing state of the society, the claims upon it, and its resources, with a passing comment therein by Mr. Bacot, the acting treasurer, who alluded to the rigid investigation now being made by the finance committee, as to the best means of rendering most beneficial and permanent the means at the disposal of the Society. Donations were then announced to the amount of £125. 11s. Dr. Burrows, chairman of that committee, though of course he would not anticipate any of the results of its deliberations, took the opportunity of reminding the members of the

Society in general, and the Court of Directors in particular, of the very effectual service they might render the Society, and through it to the profession, by giving their attendance at the half-yearly and quarterly courts, and by promoting the extension of the Society among their friends with such zeal as their personal experience of the good it was the means of doing would then imperatively call upon them to manifest. A comparative view of the state of the Society's funds, and the number of its members at different times, led unavoidably to the conclusion, that its well-being or otherwise depended in great measure directly on the exertion of its members; and he trusted that a beneficial impulse had recently taken place, which would be permanently and advantageously continued.

Sir Henry Halford presided with his usual good taste during the early part of the evening, and announced the sixteenth donation of 10*l.* from H. R. H. the Princess Sophia. On his leaving the chair, it was taken by Sir Charles Clarke, who gave the healths of Dr. Turner, Dr. Merriman, and other warm supporters of the society; and in returning thanks for the cordial manner in which his own health was welcomed, expressed, with so much genuine emotion, his love for his profession, and his feelings towards the members of it, as deeply affected all present who knew how the truth of his assertions had been borne out during a long life marked by undeviating integrity, and a studious regard for the honour and welfare of every professional man who has ever, in his person or in his character, been placed in relation to him.

OBSERVATIONS ON THE DISEASES OF CHILDREN.

BY DR. COLLIN.

THE balance of the system is more easily destroyed in children than in adults; but it is also more easily restored; their diseases far more readily become violent, but are likewise more readily overcome. Nature is here often sufficient of herself, when she can act undisturbed. Hence in children's diseases, the physician must not be too quick in prescribing medicines, particularly when the indisposition is slight, nor give those which are violent; he should rather be passive, and adopt the expectant method, taking care, nevertheless, to watch the patient's condition, lest he should overlook the cases where it is necessary that art should interfere. But if the physician is driven by the parents or friends to prescribe something from the druggist's shop, against his will, he must choose some remedy,

which is very mild, and at the utmost promotes the secretions and excretions a little; for instance, a very weak solution of tartar emetic, a solution of acetate of potash, a saline emulsion, &c. When diseases have been improperly interfered with, and brought into such a confused state that nothing remains but an impenetrable chaos of symptoms, we advise, with Tourtual, that all remedies should be discontinued, and that the practitioner should merely watch the patient's state, until the influence of accessory circumstances has ceased, and, what was doubtful in the symptoms gradually disappearing, the nature of the disease becomes manifest. Moreover, there are several disorders, such as small-pox and whooping-cough, which have their fixed course, and which can very rarely be shortened by any remedy; so that it would not only be useless but hurtful to torment the child with physic, if other circumstances do not demand it. In the case of a sucking infant, there is another point to be considered, which often causes the medicine given it to be of no advantage; namely that the disease of the child lies in the mother or wet nurse. We sometimes see that during lactation the mother becomes healthy, while the child falls sick. Unwholesome food and drink, the occurrence of the catamenia, or emanations of the mind, may alter the mother's milk, and thus be of most dangerous consequence to the infant.

A child, aged six months, was attacked by an eruption every four weeks; and various medicines were given both to nurse and infant, without the smallest effect. At last the nurse was changed, and the eruption suddenly ceased, without the use of any medicine. The fact was, that the previous nurse had an ulcer on her foot, which she did not mention, and the eruption occurred each time during her catamenial period. It is obvious how useless it must be in such cases to give medicines to the child; they must be taken by the nurse, and if the disease still continues, the nurse must be changed.

Action of Medicines on Children.—A remedy which in an adult of firm and dry temperament would have little or no effect (except raising the pulse a few beats), may act most powerfully on a child, and may even be sufficient to excite violent fever. It often happens, therefore, that we attain our end in children's diseases much sooner by mild remedies, such as dietetic ones, than by medicines properly so called; and we see daily that a proper regulation of the diet and regimen, in harmony with the character of the distemper, is sufficient to overcome it. This is particularly true among the poor, when their children are suffering under chronic diseases, which

often arise from bad nursing, or inappropriate diet. But if the child's state really requires medicine, we must always begin with a mild one, and never use a violent one, except with the greatest caution and in small doses; for at first we do not know the individual constitution of the child, which may have as many anomalies as that of an adult. If the child has an excess of sensibility, it will be powerfully and dangerously affected by small doses of volatile remedies, particularly if they contain a narcotic substance; on the contrary, remedies are of small force with a child of predominant reproductive power. Thus, Jahn saw a drop of tincture of opium produce ten hours' sleep in a child eight days old; and Voigtel saw the most critical symptoms produced by a quarter of a drop in a child born at the full time.*

Many cases, no doubt, will be advantageously cleared up, as soon as the practitioner accurately examines the habit of the child, and inquires into the constitution of the parents; but this is not always sufficient, and may often deceive. The general rule is, that in the diseases of children we must use medicines but sparingly, and follow the expectant method, particularly in the exanthemata and acute diseases. But there are exceptions; for in some maladies, especially hydrocephalus and cramp, energetic treatment must be employed.

As children are so easily affected by remedies, practitioners have thought themselves authorized to fix the doses of medicines according to age. This is considering a child as a miniature of an adult. But, in truth, the child's frame differs not only in the size of its organs, but in their quality, form, and intimate relation; from which it follows, that a remedy acts differently, not only from its dose but also by reason of its quality. This inequality depends more on the physiological state of the organs than on age. Moreover, the process of development causes great inequality in the effect of remedies, without taking into consideration the individual constitution of the child. Hence it is quite impossible to lay down a general dose of a remedy which shall be applicable to all cases; and if a table of this kind is practically useful to a certain extent, each class of remedies requires its own rules, without even referring to the periods of development. In order to set this forth more clearly, we will briefly go through the different classes of remedies †.

* It is scarcely necessary to remind the reader that the tincture of opium is by no means of the same strength throughout Europe. In the Saxon Pharmacopœia, if we recollect aright, it is more than double the strength of the London tincture.

—TRANSLATOR.

† Only two classes of remedies are commented

Volatile stimulants.—It follows, from the irritability of children, that these medicines act strongly upon them. It often happens, too, that this irritability is increased by disease, and yet the strength of the little patient has sunk so much that the less experienced physician is easily, but erroneously, led to give stimulants: experience, however, teaches that this state of weakness is often only apparent, and is caused by the living forces being obstructed in their action without being depressed; so that the weakness will not be removed by stimulating these forces, without removing the obstructions in their way. Hence it is not every stimulant that suits a child. This is particularly true of wine, the ethers, ethereal oils, and plants which contain similar substances, preparations of ammonia, and camphor. Many children have an idiosyncrasy which revolts against camphor, so that their face becomes pale after taking it, with restlessness, anxiety, and dyspnoea; and their condition is rendered much worse. Yet cases may occur where such remedies are necessarily indicated; but the physician must then be very cautious, and give them in combination with such medicines as will deprive them of their heating quality. He must begin, too, with the weaker remedies, and proceed only by degrees to the stronger ones; which, however, in many cases cannot be dispensed with.

The following remedies of this class are very useful for children:—

1. *Saffron*.—This is undoubtedly a stimulus to the vascular system, increasing the warmth of the body and adding to the liveliness of the senses; hence it must be used with caution if the patient is feverish, but it is a very soothing nervous remedy, and does not cause constipation. The physician who knows how to estimate the efficacy of saffron, will often be able to dispense with opium, which is, in general, an adventurous remedy in children's cases. Saffron is one of the principal ingredients in Hufeland's *Kinderpulver* (children's powder); besides which, we have the syrup of saffron, which is composed of saffron, sugar, and water. It has a pleasant taste, and is a valuable preparation.

2. The *Liquor ammonii succinatus* stimulates the circulation of the blood, and must therefore be used with caution in fevers; but it is very antispasmodic, removes excitement of the nervous system, and acts strongly upon the skin. Children bear this remedy very well, even sucklings; and even gastric disease, or a state of inflammation, is rarely a contra-indication to its use. It is of excellent service in spasmodic states, flatulent colic, tympanitic

upon in the present article; but a continuation is promised.—TRANSLATOR.

swelling of the abdomen caused by spasm, and towards the end of diseases, when the practitioner wishes to act on the skin and stimulate at the same time.

3. Several German Pharmacopœiæ contain another preparation under the name of *Liquor ammonii anisatus*, or *Alcohol ammoniæ anisatus*. According to the fifth edition of the Prussian Pharmacopœia, it is prepared with four ounces of concentrated spirit, a drachm of oil of aniseed, and an ounce of caustic solution of ammonia. This preparation, likewise, is a very suitable remedy for children, acting as a stimulus, but more gently than the *Liquor ammonii succinatus*; it is antispasmodic, soothing, carminative, and sudorific. When given in small doses in a mixture with some aromatic water and a little pleasant syrup, it is an agreeable medicine to take. It is suitable in the same cases as the former one, and is of particular efficacy in catarrhal affections of the lungs and trachea, in the stage where the secretion of mucus is increased, and we find, from a rattle in the breathing, that the mucus is not easily coughed up. Small doses are, on the whole, much better than large ones; it is administered to an infant at the breast, in the dose of two, or at most five drops every two hours, combined with fennel water and syrup of mallow, or with the addition of *Liquor ammon. succin.*, or *Vin. Antim. Tart.* For external use, a drachm of the *Liq. ammon. succin.* may be mixed with half an ounce of *Ung. nervinum*,* and a bit the size of a hazel-nut may be rubbed, morning and evening, on the abdomen and chest. This is a very useful antispasmodic, soothing, and carminative remedy, when there is no fever present.

Tonic remedies.—These are commonly employed to restore the strength which has been lost in maladies of long duration, but they are rarely wanted for this purpose in children, because their convalescence is generally rapid, and if a proper diet is used, may be left to Nature; nay, after violent inflammatory diseases, they are injurious, and might cause a relapse. Hence, with children, an after-course of bark, iron, or bitters, must not be too hastily adopted.

1. *Cinchona* is less indicated than in adults; with the exception of a few diseases, such as intermittent fever, and the last stage of hooping-cough. When given in substance, older children digest it with difficulty, and infants at the breast not at

all; as an extract, it causes flatulence, colic, nausea, vomiting, and congestion in the head; but most of these inconveniences are avoided by the use of the sulphate of quinine. This medicine is more easily digested, and can be more conveniently given to a child. Moreover, it is not so much contra-indicated by gastric symptoms, and is most excellent in intermittent fevers, especially in masked and malignant fevers, where life is often rapidly extinguished before the gastric irritation is removed, unless large doses are given before the next paroxysm, which are then always sufficient. Dr. Collin generally gives a mixture, composed of eight or ten grains of sulphate of quinine in two or three ounces of water, with eight or ten drops of [dilute] sulphuric acid to make it more soluble, adding enough syrup to disguise the bitter taste; a tea-spoonful is the dose, and as much is given as is requisite for the object required. Tortual prefers it in the form of powder, with sugar; and gives a sucking infant a quarter of a grain, and older children from a half to a whole grain every two or three hours. In spite of these advantages the remedy has its inconveniences: it is a strong stimulus to the vascular system, and increases congestion in the head; nay, some French writers assert, that they have seen it produce inflammation of the stomach.* In this respect it may be compared with spirituous and ethereal remedies. Indeed, the author has seen large doses of quinine produce a state in children entirely resembling intoxication from spirituous liquors. Hence, its use requires great caution, particularly in children with predominating irritability, during inflammatory fever, and during teething. Moreover, though it possesses tonic powers in a high degree, it does not contain all the constituent parts of cinchona; it acts more quickly and strongly, but not so lastingly. Hence, quinine cannot be a substitute for cinchona in every case.

2. *Iron* is in the highest degree tonic and strengthening, but must be used in children with the greatest caution. It stimulates the vascular system very forcibly; augments the rapidity and strength of the circulation; and is apt to cause ebullition of the blood, and congestion in the head. Its secondary action is upon the whole frame. Iron gives it greater energy and activity; increases plasticity; gives every organ greater firmness and strength; and diminishes secretion and absorption. It requires strong digestive powers, being apt to cause nausea, vomiting, cardialgia, colic, and tympanitis. Its use, therefore, is quite

* Gray says, in his Supplement to the Pharmacopœia, (4th edit., p. 458) "*Ung. nervinum. ol. laurini, 3 lb., ung. sambuci virid. 1 lb., axungie, 2 lb., ol. succini, 4 oz.*: the original ointment had a number of herbs, boiled in *ol. nervini, lb. v., seri, lb. ij.*, and was scented with *ol. spice 1½ oz.*"

It is obvious, that the doses recommended by Drs. Collin and Tortual are far too large. Half the quantities proposed in the text would still be more than ample.—TRANSLATOR.

inadmissible in those diseases of children where there was already increased plasticity, and unusually violent irritability; moreover, it is very hurtful in gastric disorders: Nor should iron be given to children of a sanguine temperament, or to those who have a very irritable vascular system; or suffer from a sub-inflammatory condition of the lungs; or who have great irritability of this organ, with a disposition to phthisis florida. But there are some diseases of children where this remedy is not only beneficial but indispensable; namely, in atonic scrofula and rickets; in children with a pale and puffed face, great flabbiness of the limbs, diminished irritability, and excess of serous and mucous fluids; and, in general, in all dyscrasias, founded on a watery, leucophlegmatic quality of the blood and the lymphatic fluid. It here appears to penetrate both the fluid and solid parts, making the blood thicker, and richer in red particles, and the complexion more blooming. It gives firmness and strength to the irritable fibre, and a higher degree of tension to the cellular substance and the skin; and, by its tonic qualities, it removes obstructions and swellings, caused by atony in the glandular and vascular system. The mild preparations of iron in the Swedish Pharmacopoeia are:—*trochisci citratis ferri*, *tartras kalico-ferricus*, *murias ammonio-ferricus*, and *hydras ferricus*. The *vinum ferricum* is more stimulating as a medicine for children, because it contains cinnamon and wine. The *ferrum pulveratum* is not easy to digest, being apt to cause nausea, pain in the stomach, constipation, and other gastric symptoms. It should seldom, therefore, be given to children, and never without the addition of aromatics, although they increase irritability.—*Schmidt's Jahrbücher*, from the *Tidskrift för Läkare*.

PREMATURE LABOUR ARTIFICIALLY INDUCED IN A DWARF.

By M. DUBOIS.

THE subject of this case is a dwarf, æt. 23, 3 feet 2 in. 9 l. high, whose father was only 3 feet 6 in., but whose mother was of ordinary size. These, her parents, had six children, of whom three were dwarfs. Two years ago, M. Dubois attended her in her first labour; when he was called in she had then had pains for 48 hours; on the previous evening she had had convulsions, and she lay in a kind of stupor in a *cradle*. The labour appeared in an advanced stage, for the child's head could easily be felt in the hollow of the pelvis; but further than this it could not pass, and the forceps

could not be applied. The child was evidently dead, and M. Dubois, therefore, perforated the head, and it passed on to the vulva. Here, however, there was a fresh difficulty, for the vulva was narrow in correspondence with the stature of the individual. Happily, it soon enlarged spontaneously by a rupture which passed backwards and on one side towards one of the ischia, and the labour was terminated. The child, without its brain, weight 5½ lbs; its length was 7½ inches. The patient went on satisfactorily after the labour, and soon recovered. The state of stupor in which she was at the time of the *accouchement* almost prevented her feeling the pains.

Last year, she again became pregnant; but this time, (says M. D.) in conformity with my recommendation, she came to announce it to me early. She had, when she came to me, been pregnant since about last June; and I found by the examination of the pelvis, that its diameters were not proportioned to the presumed dimensions of the fœtal head, for the pubo-coccygeal was not more than 3 inches.

Admitted to the obstetric clinique, we found on examination, that the uterus was but little developed and the fœtus small. In February, she was in the eighth month of her pregnancy; and the abdomen then enlarged considerably in the space of a few days, so as to cause some fear that the *accouchement* might be rendered difficult by a superabundance of liquor amni. Having decided on inducing premature labour, I had to choose between rupture of the membranes, dilatation of the neck of the uterus with prepared sponge, and the administration of the ergot; I decided on the two last. The patient having taken a bath, was placed on the edge of the bed, and a speculum was introduced; a portion of prepared sponge, an inch long, and cut in the form of a cone, was placed in the neck of the uterus, and over it another moist sponge to keep it in its place; they were fixed by a thread, and six grains of ergot of rye were administered. The patient was then put to bed. Four hours after, she felt strong pains, and was in active labour; it appeared indeed to be going on so rapidly, that I withdrew the sponge. At nine in the evening, there was a full protrusion of the membranes, and I ruptured them and found that the buttocks presented. The fingers were applied on the haunches to facilitate their exit; the head remained at the superior aperture; drawing downwards a few times, and movements of flexion, brought it into the hollow; and at last it came out entirely. The child breathed immediately; it was 15 inches long; the biparietal diameter was 3 inches; the

occipito-frontal 3 inches and 2 lines: it weighed 3 lbs. 12 oz. The size of the child was therefore small: yet it was not a dwarf. The mother nourished it for a few days, but the secretion of milk soon ceased: on the twentieth day the woman was perfectly recovered.

M. Dubois adds some details as a supplement to this history. The father of the child is a man of ordinary stature; he is about 5 feet 7 inches high. The first sexual connections were very painful: but the periods of pregnancy were easy.

Nothing is more rare than the accouchement of dwarfs: for there is but a single authentic fact, which is related in the work of Geoffrey Saint-Hilaire. The woman, who was to have been confined at London, died. It is to be observed, that the child of this woman is not a dwarf: dwarfs are born much smaller. The mother herself was born extremely small; she passed all her infancy on a table seated on a cushion. There is but one exception to this rule, an English dwarf exhibited in 1770; he was born of the usual size, but at the age of one year his growth was suddenly arrested.

I have, of course, no need to justify the measure which I adopted in this case. It cannot be compared with an operation, of which the result would be to sacrifice the mother or the child, or both at once. More than two hundred cases that have now come to my knowledge, prove that the plan I adopted is not so serious a thing as might be imagined; half the infants, and an immense majority of the mothers, have survived it. Still, the Cæsarean operation is certainly not in all cases to be superseded by the production of premature labour; each of these operations, as well as the division of the symphysis, and embryotomy, has its own special indications. — *Gazette Medicale, Mars 14, 1840.*

SUCCESSFUL TREATMENT OF A CONGENITAL UMBILICAL HERNIA.

By Prof. CEDERSCHJOLD, of Stockholm.

THE umbilical ring was open in this case, and had probably a diameter at least of an inch, through which the intestines, covered only by peritoneum, protruded, and formed a mass as large as a fist. The umbilical cord came out from the most prominent part of the tumor. The protruded intestines could not by gentle pressure be returned into the abdominal cavity through the ring, and it was by chance discovered that they were full of meconium, which the child had not yet evacuated. A laxative medicine was therefore ordered

to be introduced, before the intestines were replaced. Five teaspoonfuls of castor oil were given before the bowels acted; the hernia then became soft; and by placing the child on its back, its reduction was easily accomplished. The sac, consisting of the peritoneum only, being emptied, a ligature was tied close to the umbilicus, which falling off after 14 days, the navel was found completely healed, and just like that of a healthy child. — *Schmidt's Jahrbucher.*

SOUNDS OF THE HEART.

To the Editor of the Medical Gazette.

SIR,

I PERCEIVE that Dr. Billing, in making some remarks upon the causes of the sounds of the heart, in the MEDICAL GAZETTE for the 3d of this month, accuses Dr. Todd of having *misrepresented* his opinions on that subject, in the article "Heart, in the Cyclopædia of Anatomy and Physiology." As I am the author of that article, and therefore responsible for its contents, I consider myself called upon to exonerate Dr. Todd from this charge brought against him by Dr. Billing. The complaint made by Dr. Billing is, that in the article alluded to, he is represented as attributing the first sound of the heart to the rapid approximation of the auriculo-ventricular valves during the systole of the ventricles; while in fact his opinion is, that it depends upon the tension produced in the shutting of the auriculo-ventricular valves.

As in writing such an article, it would neither have been interesting nor profitable to notice at any length the speculations of every one who had written on the sounds of the heart, I was obliged to classify them as much as possible; and as Rouanet, Dr. Billing, Mr. Bryan, and M. Bouillaud, had all supposed that the first sound was due to some of the changes induced in the condition of the auriculo-ventricular valves during the systole of the ventricles—an opinion which I believed to be fully disproved by experiments to be afterwards mentioned—I thought it sufficient to say, that these authors referred this sound to the rapid approximation of these valves, without entering into each individual explanation, as to whether this was produced by the tension of these valves, or by the flapping of them together.

I beg to assure Dr. Billing, that the cursory manner in which I have noticed his opinion on the cause of the first sound of the heart, is due to the circumstances mentioned, and assuredly not to the slightest desire or intention of misrepresenting it.

JOHN REID, M.D.

Royal Infirmary, Edinburgh,
April 13, 1840.

IRISH PHYSICIANS.

(From a Correspondent.)

By the charter of the Irish College of Physicians, no person is permitted to practise as a physician in Ireland, unless a licentiate of the College, or a medical graduate of the University of Oxford, Cambridge, or Dublin. This prohibition, not being confirmed by act of parliament, has heretofore, been considered as nugatory; but an eminent lawyer, it is said, takes another view of the matter, and considers that, as the authority of the Irish College of Physicians, and of all the Universities of the empire, emanate from the same source, the Crown, the negative and positive enactments thence proceeding must be put on a level; and that therefore, whatever right a medical degree confers as to practice in general, the license of the Irish College of Physicians, or a degree of one of the Universities first mentioned, confers, as to the exclusive right of practising in Ireland.

ETHEREAL SOLUTION OF ERGOT.

To the Editor of the Medical Gazette.

SIR,

HAVING had numerous applications made to me by members of the profession, desiring to know where they can obtain the "Ethereal Solution of Ergot," an account of which you so politely inserted in your journal of the 10th inst.: may I be permitted to inform them, that it is now prepared by Mr. Dear, pharmacist, 89, Bishopsgate-street Within.—I am, sir,

Yours most truly,

JOHN C. W. LEVER,

Ass. Accoucheur to Guy's Hospital
Lying-in Charity.Guy's Hospital,
April 21, 1844.

RECEIVED FOR REVIEW.

The Library of Medicine, arranged and edited by Alexander Tweedie, M.D., F.R.S. Vol. I. Practical Medicine. Whittaker and Co. 1840.

A Treatise on Amaurosis and Amaurotic Affections. By Edward Octavius Hocken. Higley, 1840.

A Natural History of Quadrupeds and other Mammiferous Animals. Part III. Whittaker and Co., April, 1840.

Odontography, or a Treatise on the Comparative Anatomy of the Teeth. Illustrated by upwards of 150 plates. By Richard Owen, F.R.S. Part I. containing seven sheets of letter-press and fifty drawings by Mr. J. Denkel, and engraved by Mr. L. Aldous. Baillière, 1840.

Commentaries on Diseases of the Skin. Illustrated by coloured plates. By Anthony Todd Thomson, M.D., Professor of Materia Medica and Therapeutics, and Medical Jurisprudence, in University College, London. Fas. III. representing Pityriasis, Herpes, and Rupia. Taylor and Walton, 1840.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF TENDONS, *continued.*

CLUB FOOT, *continued*—*Reparation of Tendons—Appreciation of means of Treatment.*—*PERMANENT FLEXION OF THE LEG—Causes—Treatment.*—*WRY NECK—Nature—Causes—Treatment.*—*STRABISMUS.*—*RETRACTION OF THE FINGERS—Nature—Causes—Treatment.*—*Diseases of Tendinous and Subcutaneous Bursæ—their Nature and Treatment.*

THE section of the tendo-achillis having been made, the work of reparation soon commences. For many hours after the operation the extent of separation is very distinctly felt; after that, the tumefaction of the surrounding tissues contributes to fill up the space, and as the tumefaction diminishes the secreted and extravasated fluids accomplish the same objects, so that by the tenth to the twelfth day the continuity of the tendon seems established. From a fortnight to three weeks is necessary before the intermediate substance is sufficiently resistant to admit of strong flexion of the leg, and from this moment the patient may walk with little assistance at the part. The feebleness of the muscles causes the walk to want assurance, but practice soon improves it.

In brute animals, the dog for instance, we find, if we sacrifice an extensor tendon, that at the end of the second or third day the cellular sheath is thickened and inflamed, sometimes full of blood, and that

this blood is transformed into a compact coagulum, which is confounded with the extremities of the tendon and the surrounding parts; if much blood be not effused, an albumino-fibrinous mass is formed and occupies the same place: the extremities of the tendon contract, as if surrounded by a ligature, the intermediate substance is condensed by the twelfth day, but the ends of the tendon are, up to that time, quite distinct from it. By the eighteenth day this substance forms a cord as large as the tendon, and strongly adheres to its extremities; by the twenty-fourth day the intermediate substance is fibrous, its fibres seem continuous with the tendon, it has great power of resistance, and all inflammatory action is dissipated; by the thirtieth to the thirty-fifth day the continuity is perfectly established, but the difference in their appearance is still marked. Bouvier believes this intermediate substance is not formed by extravasated lymph, but by an adaptation or transformation of cellular tissue. This difference is practically unimportant; there is no dispute about the solidity of the union, and the nature of the cicatrix. But the section of the tendon is in most cases a small part of the treatment necessary for club foot: extension by mechanical means must follow, and I know no apparatus more generally available for the purpose, than the following (fig. 1), invented by Stromeyer: but this apparatus is more particularly available to procure the necessary extension in *pes equinus*:—where lateral deviations exist, whether *varus* or *valgus*, then the following modification of Scarpa's apparatus will be found to answer better, by enabling the patient to move about with more facility during the cure (fig. 2).

It is vain for surgeons to object in the present day, that it is dangerous to destroy the continuity of the tendo-achillis. A sufficiently extensive experience proves that it is in every way superior to those

FIG. 1.

FIG. 2.

fatiguing machines which up to this time have been in common use. But this operation will not succeed if there be any abnormal union between the tarsal bones, or at the ankle-joint, and only partially if there be any deformity in those bones themselves, though a new position may do much to remedy this. Properly used, it is established that it is applicable to all ages and both sexes, since it has been performed with equal success from early infancy to fifty, in women as well as men. A month, or two months, will commonly suffice for a cure, that is, for the patient to walk on the sole of the foot; a longer time will of course be necessary to dissipate the more prominent traces of the deformity. It is true that some of the patients who have been cured by it might have been cured without it, by means of the machines of Scarpa and others, or by enveloping the limb in plaster of Paris: but then this operation is so simple, so free from pain, so easy, and so exempt from danger, its results are so prompt, so complete, that unless there be great objections on the part of the patient, it should be generally substituted for the different apparatuses which were almost exclusively employed up to the present day.

It must not, however, be supposed that because the mechanical has ceased to be the principal method of treatment, it is therefore to be entirely abandoned; its value is little less because it is made to play the part of an auxiliary. It is still an indispensable element, so much so, that the perfection of those apparatuses and the exactitude of their application are in many cases a *sine quâ non* of a perfect cure, and the insufficiency of mechanical means is an occasional source of failure of the operation. The power of mechanical means, associated with section, in the reduction of these deformities, has scarcely any limits, when the osseous surfaces are not continuous, and the moral courage of the patient secures the care of the operator. Still, I do not hold out to you the section of the tendo-achillis as an exclusive method, preferable in all cases to every other. The principle to be kept in view in the application of mechanical means, whether before or after section, rests on the same basis; the centres of motion of the apparatus must correspond to the centres of motion of the displaced joints, and its action must be exactly opposed to the action of the retracted muscles.

RETRACTION OF THE LEG.

The same causes which produce retraction of the foot may produce retraction of the leg, but there are other causes by which the femoro-tibial region may be affected. Retraction in this region may be brought about by disease around the joint, not im-

plicating the tissues of the joint itself to any serious extent; by phlegmonous inflammation of the cellular tissue around the joint, by long inaction, the limb being kept in the flexed position, by gout or rheumatism—in fact, by any cause capable of inducing rigidity in the soft parts around the articulation. This rigidity may affect only the tendons destined to move the leg upon the thigh, or it may be accompanied by a similar condition of the ligamentary tissues. In a certain number of cases the contraction has seemed to depend principally or almost entirely on the resistance offered by the tendons of the hamstring muscles, and in these cases the section of one or more of these tendons offers a probable remedy for the disease. But before we resort to operation, we must be satisfied that the ankylosis is extra-capsular, and that the tendons and not the ligaments are principally affected: some persons are of opinion, that even if the ligaments be affected, we ought not to hesitate in attacking them; but before I advise you to apply a cutting instrument to the ligaments about the knee-joint, I should like to support my advice by experience.

Michaelis applied his "partial section" to this disease, but he has not described his mode of operating. Stromeyer, Dieffenbach, Duval, Little, Liston, and no doubt many others, as well as myself, have employed this operation, with varying and more or less complete success. Lutens also employed it, but his operation did not consist of a subcutaneous section; he fairly cut his way out through tendons and integument, making a large wound. In none of the cases published in the *Thèse* of Duval, amounting to seven, did the patients exceed the age of 35; the respective ages being eleven, twelve, six, two, twenty, thirty-five, and twenty: the disease which produced the condition being respectively, phlegmonous inflammation, with abscess around the knee joint; the second, a similar affection, consequent upon local injury; the third, paralysis, consequent on meningitis; the fourth, suppurative inflammation around the joint; the fifth, severe subcutaneous inflammation; the sixth, paralysis; the seventh, suppurative inflammation. Lutens' case was a consequence of inflammatory action, succeeding to contusion. Dr. Little's case had succeeded "to caries and suppuration around the joint." My cases succeeded to rheumatism. In fact, it does not seem to me material what caused the condition; if we find that the hamstring muscles evidently prevent further extension, if we can flex the leg so far as to assure ourselves that true ankylosis does not exist, and there be nothing about the joint, at the time, to contra-indicate operation, we may, ordinary exten-

sion failing, make the section of the hamstring tendons.

The operation is performed in the following manner:—the patient lies on the abdomen, with the thigh extended; the surgeon places himself on the side of the tendon he is about to cut. If he be about to divide the biceps, he makes his puncture on its outside, if the inner tendons, the puncture must be made on their inner side. The knife is passed under the tendon, or between it and the integuments, and when it has arrived on the other side of it an assistant extends the leg so as to make the muscles very tense; the cutting edge is then turned towards the tendon, and, by means of a slight sawing motion, rapidly divides it. Supposing we are operating on the biceps, the operation is now finished, the knife is removed, and the little wound dressed. If the inner hamstring tendons are to be divided, the operation is not so easy; we may have to cut the tendon of the gracilis, the sartorius, the semi-tendinosus, one after another; and this is scarce-

ly more difficult or dangerous than the biceps—the artery, vein, and nerves, are too deep-seated to be in danger. The internal saphena vein and nerve run some risk, but they are easily avoided. Unfortunately, when we have done all this, we may find that the tendon of the membranous requires to be divided. Placed near the posterior surface and inner border of the femur, towards its termination, it is necessary that the instrument, carried between its posterior surface and the tendons we have mentioned, should be so held as to divide the muscle from within outwards and forwards, about an inch above the inner condyle. If we use a blunt-pointed knife there will be little risk of injury to the popliteal vessels and nerves; and if we find that any resisting portion still remains, it must be divided. As soon as the operation is completed, extension may be increased considerably; but I prefer leaving the limb at rest for three days, when extension may be commenced by means of such an instrument as the following, which I employed in my case.

Extension should be slowly made, and the revolutions of the screw should not exceed two daily, and even that, in some cases, may be more than the patient can bear. In most cases it will be found that extension may be carried to its extreme limits within six weeks; sometimes it may be accomplished in half that time; in others, as in one of Duval's cases, many months may be necessary for the purpose. It is not wise to make pressure over the patella, because patients usually complain of it, and it has interfered with the progress of the cure. If there be anchylosis at the knee-joint, the section of these tendons must not, of course, be attempted, nor, indeed, unless the flexion be exempt from luxation—unless, in fact, the infirmity be owing to a retraction of the muscles. In this point of view, flexion of the leg has not been sufficiently studied to enable us to determine whether one of the hamstring tendons more than the other has a tendency to become thus affected. However, this is not a difficulty in the operation, because

the surgeon divides those only which prevent extension of the leg.

WRY NECK, CAPUT OBSTIPUM, OR TORTICOLIS,

may be produced by several causes; but the most common would seem to be a retraction of one or more of the muscles of the neck, usually the sterno-mastoideus. The idea which long existed that wry neck was always the consequence of anchylosis, or some other affection of the spine, has had much influence in the treatment of this affection; despairing of cure, palliatory measures were alone employed. In the present day, we seem to be precipitated into the opposite exaggeration: many practitioners maintain that wry neck is always owing to muscular retraction. A midway course between these discordant opinions is the one you must follow: some cases of wry neck are undoubtedly owing to changes brought about gradually in the relation of the articulating surfaces of certain of the vertebræ of the

neck; others are as certainly owing to exaggerated muscular action alone; and, unfortunately, in a given case, it is difficult to say whether the deformity is owing to one or the other. A cicatrix and chronic deep-seated inflammation of the tissues of the neck may also produce the disease.

What we have said, in speaking of muscular retraction generally, and the destruction of equilibrium, perfectly applies here. On one side a muscle may be paralyzed, on the other, its power may not be increased; yet wry neck may be the consequence: or, on one side, the power is abnormal; on the other, is exaggerated—from this may result wry neck; it may succeed to rheumatism, to neuralgia, to scarlet fever. When caused by rheumatism, and treated early, it is often cured by counter-irritation, local bleeding, or emollients; but when it is of nervous origin, or has succeeded to chronic inflammation, it will not yield to such means. The muscle most commonly contracted is the sterno-cleido mastoid—more particularly its sternal attachment, or, to speak more correctly, the sterno-mastoid, for there can be no question that the functions of the sternal portion are distinct from the clavicular; the first is especially the motor of the head; the other is essentially a muscle of respiration. In wry neck it has been usually the fashion to consider it as dependent upon a retraction of the *sterno-cleido mastoid* muscle, whilst it is the *sterno-mastoid* alone which is usually and primarily affected; it is this portion, therefore, particularly, which it is necessary to attack in treating the affection. Still it is not only the sternal portion of this muscle which must be occasionally attacked; it may be necessary to act upon the clavicular portion, or even the clavicular portion of the trapezius; examples of this are given by Gooch, Sharp, Stromeyer, and others. Out of the thirty seven cases mentioned by Dieffenbach (*Berlin Medic. Zeitung*. 1838, No. 27), in twenty-four the whole muscle was affected, so that in so large a proportion of his cases the section of both attachments of the muscle was necessary.

There are two kinds of deformity to which the term wry neck has been attached; in the one the head is rotated; in the other, it is simply inclined. The rotation occurs from the healthy side, the muscle of that side being hard, projecting, and often painful; spontaneous motion of the head is impossible; in fact, to reduce the head to its proper position, considerable force is necessary, and, as soon as the force is removed, the head returns to its former position. There is a variety of this deformity which has an intermittent character, and, in these cases, there is usually no vertebral disease; there is another in which the

disease is convulsive, or spasmodic, which may be permanent.

Treatment.—These deformities, when dependent upon muscular contraction, and when there is no spinal disease, will sometimes give way to counter-extension continued for some weeks, but the benefit is often only partial—the deformity is only partially removed. I know at this moment two patients, in whom the deformity has succeeded to scarlet fever, and has been treated in every conceivable way short of section, and with very little benefit.

Within a few years, Recamier has proposed a method of treatment, which, in such cases, in his hands, has succeeded very well, and which he terms massage. It consists in making sudden jerks, to the extent the muscle will allow, in the direction to reduce the deformity. In many cases, in a comparatively very short space of time, the muscular contraction is overcome, and the head restored to its proper situation; but the pain attending the practice is often very severe. He has also employed, with considerable success, a method which consists in a sort of shampooing of the affected muscle.

In the treatment of this deformity we find that surgeons long ago resorted to the section of the *sterno-cleido mastoid* muscle. Among the early operators are Isacius Minius, mentioned by Tulpus, (*Observat. Medic.*, 1641; Roonhuysen, (*Heilkuren Nürnberg*, 1674); Meekren, (1688); Blasius, 1677; Sharp, 1739; Cheselden, 1740; Gooch, 1757; but, after his time, the operation was not, so far as I know, resorted to until 1822, by Dupuytren.

In 1822, a case of this deformity was presented to Dupuytren at the Hotel Dieu. "Massage" and topical relaxants were tried without effect, when that celebrated surgeon determined to make a section of the *sterno-cleido-mastoid* muscle, which was in a state of permanent retraction. To avoid an unsightly cicatrix at the internal border of the inferior attachment, he made a small puncture, through which he passed a narrow blunt-pointed bistoury, flat, behind the muscle: when it fairly included the muscle, he turned the cutting-edge towards it; and cut through its fibres, passing towards the skin, without wounding it. The head was quickly restored to its proper position, and there was no drawback. In 1833, Professor Syme performed the operation in a child of six months: the wound was excessively small, the cure immediate and complete. Now, the operation of Dupuytren was chronicled in 1823, in Germany, in Ammon's *Parallele* (Leipzig); near the same time in England, by Mr. Averill, in his *Operative Surgery*; by Froriep, of Weimar, in the same year; by Graefe and Walther in 1824; by Dieffen-

bach in 1830: and yet, in 1838, we find two eminent French surgeons, one of whom did not perform the operation before 1836, the other before 1837, strongly supporting their several claims for inventing the operation.

The operation is now performed in the following manner:—The patient is either laid on a table, or sits in a chair; the head is slightly flexed, so as to admit of the knife more easily passing between the integument and the muscle. The surgeon having placed himself in front or at the side of the patient, with the right hand, if it be the left side, the left if it be the right, he makes, if we follow the plan of Guérin, a puncture at the external border of the sternal attachment of the mastoid muscle, at six or eight lines above the sternum. The instrument is then passed on its flat, immediately before the muscle, until it reaches its internal border; he then turns the edge towards the muscle, and carefully cuts through it, passing towards the deeper seated parts. If it be right to relax the integuments while the knife is gliding beneath the skin, they, as well as the muscle, must be made tense at the moment of section. As the knife is acting upon a dense tissue, the absence of resistance clearly indicates when the section is completed.

For the clavicular portion the puncture must be an inch, or an inch and a half, more externally, and a little nearer the clavicle. As this portion is larger than the other, the bistoury must be carried deeper from without inwards. This tendon, which is as frequently divided from its internal to its external border, as from its cutaneous to its deep surface, is less surrounded than the sternal portion with blood-vessels. If, instead of thus dividing the muscle, commencing by its cutaneous surface, we prefer cutting from its posterior to its cutaneous surface, it will be more convenient, but not indispensable, to puncture the integuments on the inner edge of each tendon; and, when the puncture is made, I think it most prudent to use a blunt-pointed knife, so as to more surely avoid wounding the vessels of this region: afterwards, cutting towards the cutaneous surface by a short sawing motion. As soon as the tendon is cut through, a depression between the extremities is very evident. The head can then, usually, be brought to its proper position. The accidents which have been experienced are not severe; the ecchymosis is often considerable; nervous excitement has been occasionally seen; and, in one case of Guérin's, something like the penetration of air into veins; but the symptoms were not pressing. The little wound is usually soon cicatrised, and suppuration very rarely occurs. But the absence of serious accidents so far, though Dieffenbach himself has operated fifty times, must not put you

off your guard, and the operation must not be lightly undertaken. Its deeper surface is in immediate relation with the subclavian artery and vein, the internal jugular vein, and carotid artery; its superficial surface is traversed by filaments of the cervical plexus, by the external jugular vein. Other veins creep along its inferior extremity.

When the primary obstacle to the reduction of the deformity is destroyed, all our difficulties are not usually removed. The passive retraction of other muscles must be overcome; and this is to be done by mechanical means, which are to be used as soon as the little wound is cicatrised, about the third day. The head and neck having been long maintained in an abnormal position, all the muscles of the neck, not only those of the affected but those of the healthy side, have suffered changes of relation and dimension. These circumstances show evidently, that a mechanical consecutive treatment is almost as indispensable as the surgical operation. The duration of mechanical treatment is variable, depending upon the time and the extent of the deformity. Some days will often be sufficient to make an apparently perfect reduction, but many weeks are often necessary to really complete it.

It is hardly necessary to make a comparison between the present and former modes of treating wry neck. As far as concerned the former operations, either the integument was included in the transverse incision, or a longitudinal incision was made in the course of the fibres of the muscle; a director was then passed under it, and its fibres incised on the director. These two modes differ much in principle and in the mode of execution. In the transverse section, the operation was long, fatiguing, and painful. Similar inconveniences attend the second operation; the obstacles to raising the muscle upon the director, and to pass the director through the opening, are considerable. The immediate results of these two operations are relative to the time and the difficulty of the operation, the pain which is suffered, and the extent of the wound. Considerable inflammatory action has been developed, has extended to the throat and surrounding parts; the cicatrix is unsightly; it interferes with the employment of mechanical means, causes the muscles to adhere to the skin, and thus seriously interferes with extension. As to the definitive results they are not more advantageous: the reduction is incomplete; a certain rotation and inclination of the head remains, because proper mechanical means could not be promptly applied. This proves how indispensable is the consecutive mechanical treatment, and shows very clearly the advantages of the operation at present employed.

Other muscles of the neck have been cut

through for the purpose of relieving this deformity. In a case in which section of the sterno-cleido-mastoid was insufficient to admit of the removal of the deformity, Stromeyer carried his knife under the anterior edge of the trapezius. The platysma myoides underwent similar retraction in a case described by Gooch; he incised it transversely, and cured his patient. The only organ about which any risk is run in that operation is the external jugular vein. Where this kind of retraction is a consequence of a burn, this incision will be unavailing, even when associated with mechanical means.

STRABISMUS.

The principle of tenotomy has been proposed to be applied to the tendon of the biceps, in obstinate cases of flexion of the elbow joint; and has actually been applied in many cases, by Dieffenbach and others, to the cure of strabismus, with, it is said, complete success, and but trifling present inconvenience. It is assumed, that the eye is drawn inwards or outwards by exaggerated action, or retraction of the external or internal rectus muscle; and a section of the affected muscle is the remedy. The operation is performed in the following manner:—the eye-lids are fixed as in an operation for cataract; the conjunctiva is grasped by a hook close to the point to be punctured, or a small hook is passed through the sclerotic, so as to keep the eye fixed; these hooks are given to assistants. The operator then proceeds to cut through the conjunctiva, making an incision about five lines long, and about three from the cornea; he then carefully dissects down until he comes upon the tendon of the muscle, follows it back a short distance, passes under it a curved scissors, makes the section, and the eye is immediately redressed. So far the cases of success preponderate; and the only inconvenience has been ecchymosis of the conjunctiva: but I cannot help thinking, that already the operation has been undertaken without sufficient caution. How are we to determine, *a priori*, that the oblique muscle is not the seat of mischief, and that some disease, of a chronic character, within the brain, may have occasioned the strabismus. Still it is a very ingenious operation; and, if well performed, does not seem likely to produce great local mischief, even though it did not succeed in curing the deformity.

RETRACTION OF THE FINGERS.

We are occasionally called upon to treat deformities of the fingers dependent upon retraction of certain of the flexor or extensor tendons, or of the palmar fascia; but a case was brought under my notice, not long since, where there was a lateral de-

formity of the fingers, occasioned, as it would appear, by a habit, not uncommon in boys, of getting two pieces of slate between the fingers, and bringing them suddenly together, so as to make a loud noise. These cases are, I apprehend, rare; but permanent flexion of the fingers is not at all rare.

The deformities produced by cicatrices succeeding to burns are frequently seen, and, in many cases, they are owing to incomplete extension during the work of cicatrization: the deformity may be so excessive that the palmar surface of the finger may be united to the palm of the hand. Before we attempt to relieve them, we must first ascertain whether the joints or tendons are implicated; if they be not, we proceed to set the finger free by a careful dissection; but we must also remove the tissue of the cicatrix, otherwise the evil will be renewed. I saw the other day, at the Bristol Infirmary, another plan, which had succeeded, in as far as one finger was concerned. A seton was inserted through the cicatrix, and gradually cut its way out; but I think there can be no question that the operation of excision of the cicatrix is the preferable mode of proceeding. In either case care must be taken not to injure the tendons; and the hand should be placed on a finger-splint, so as to keep up the separation during the healing process, which is often long.

Every now and then we see cases where a permanent and incurable flexion of the finger may succeed to the section of the extensor tendon, or to any wound or injury which may equally destroy it. It may succeed to paralysis of the extensors; we also see it follow injuries which have for a time prevented the motion of one or more fingers. In many of these cases we can easily make a forced extension, and we may maintain them in this position; but it is very difficult, and, in many cases, impossible, to maintain, between the flexors and extensors, the necessary equilibrium.

A more frequent cause of permanent flexion is a disease of the flexor tendons themselves. A relation of my own received a slug wound in the forearm, which more or less completely cut away a portion of the flexors, and in this case there is permanent flexion or contraction of the little and ring fingers. I have known an incision made for the cure of whitlow to be followed by the same condition: in that case the sheath of the tendon was opened: the puncture of a nerve in bleeding has been followed by a similar state. In the Archives, for June, 1838, a case is mentioned where complete section of the wounded nerve immediately cured the disease.

But permanent retraction of the fin-

gers is, in the great majority of cases, dependent upon another cause, or causes, about the nature of which much difference of opinion exists. Although the ancients described the affection under the term *crispatura tendinum*, it is to Sir A. Cooper, Dupuytren, and Goyrand, that we owe all that is accurately known on this subject. The disease has a particular predilection for the three last fingers, but it more especially affects the ring finger, rarely attacking the other two until it has become pretty advanced in that. With the exception of a single case, dissected by Goyrand, I know of no other in which the thumb was affected. Dupuytren, in speaking of the disease, which certainly most commonly affects persons whose occupations oblige them to keep the hand very generally flexed, such as hackney coachmen, says, the first phalanx is flexed upon the corresponding metacarpal bone; the second is flexed upon the first; but the third very unfrequently participates in the disease. In the palmar surface of the fingers, we find projecting bands, which set out from the palm, and fix themselves to the anterior surface of the first two phalanges, and become very tense when extension is attempted; at the same time the tension is communicated to the palmar fascia. The skin presents, at the level of the roots of the fingers, semi-lunar folds, with their convexities directed superiorly.

Many different opinions exist as to the cause of this condition, some attributing it to the retraction of the tendons. Boyer said the cause was unknown; but still, in considering attentively its phenomena, and the slow and gradual manner in which it is developed, believed it depended less on a spasmodic contraction of the flexors than a species of drying rigidity, or hardening of the tendon and the skin. Sir A. Cooper attributed the disease either to a retraction of the flexor tendons and their sheaths, or to that of the palmar fascia, as a consequence of certain kinds of labour with the hand. Dupuytren dissected the hand of a person in whom the affection existed, and believed it was a consequence of contraction of the palmar aponeurosis, and the traction of the small bands into which it divides inferiorly, and which proceeds to be attached to the sides of the first phalanges. He cut through these bands, and the fingers immediately resumed their natural position. Upon Dupuytren's shewing, all that was necessary for the cure of this affection was to cut through these bands of aponeurotic fibres. In some cases this plan has succeeded, in others it has failed, and therefore we must regard this opinion as too exclusive. Goyrand shewed upon dissected specimens that it is due, not to retraction of the palmar fascia, but

to fibrous cords, which he conceives of new formation, some of which extend from the palmar aponeurosis to the sheaths of the tendons and the edges of the phalanges, whilst others extend from a point of this sheath to a point in front of the phalangeal articulations, others set out from a superior phalanx, to attach themselves to the corresponding portion of the adjoining phalanx. The existence of these bands certainly explains the necessity which has been found for making several incisions along the anterior surface of the finger.

The disease is sometimes congenital and even hereditary. In 1832, Dupuytren operated upon a child of six, who had congenital retraction, and whose grandmother had also congenital retraction; but usually, besides these predisposing causes, there are direct or determining causes. Among these are arthritic affections, sprains, wounds—in fact, all things which oblige the patient to keep for a certain time the fingers flexed. In these cases the fibro-cellular bands, which up to that time were long enough to admit of extension, are shortened, and ultimately complete extension is prevented. The more these cords project the more they are irritated by pressure, and the more they are developed, and the extending power can no longer effectually struggle against it. In the state of repose the fingers will always be found so flexed as to relax these cords, and thus the deformity increases. The retraction in these cases is very powerful. Dupuytren, in a case, sought to cure the disease by overcoming the flexion by means of weights appended to the fingers; fifty-five pounds were borne without materially lessening the flexion. In a single case he demonstrated by dissection that the palmar aponeurosis was retracted; he shewed that the folds of the skin were effaced, by cutting through the aponeurosis; that when the skin was separated from the aponeurosis the folds no longer existed; that the section of the flexor muscles and their tendons did not permit the deformity to be reduced. The objections made to this exclusive view are, that the aponeurotic prolongations proceed only to the base of the first phalanx, that Dupuytren himself was obliged to make incisions at the level of the first phalanx, and at the articulation of the first with the second. An explanation of these facts was given by Goyraud; and there can be no doubt that cases occur in which there is no disease of the palmar fascia. It is difficult to understand why, in these cases, the ring finger always suffers. The only probable explanation is, that the principle exists in the palm of the hand, in the seat of flexion; the ring finger is worse off as to extension than the others; the thumb, the indicator,

and the little finger, all have proper extensors: the middle finger has a strong one belonging to the common fasciculus, whilst the annular one has an extremely small tendon proceeding from a small muscular bundle; thus its most constant state is that of flexion, and its individual movements are very feeble and difficult. Persons who play upon certain instruments know that difficult passages are often ill executed with this finger. In almost all manual exercises, it is the two first fingers and the thumb which are used; the ring finger is flexed.

Treatment.—In the treatment of these affections, machines, emollients, stimulants, as well as section of the tendons, have been vainly employed. At present we are sensible that the only probable means of cure is section of these subcutaneous bands. Dupuytren's method was to make transverse incisions, ten lines long, at the most projecting part of each band—that is, usually at the level of the metacarpo-phalangeal articulation of each retracted finger, occasionally a little higher or lower. After the incision of the skin, the band is made as tense as possible by extending the finger, and then completely dividing it. If that be insufficient, a new incision must be made at a certain distance from the first. Each retracted finger requires a special section. Goyraud recommended to incise the skin longitudinally upon each band, previously made quite tense, to separate the lips of the incision, to detach them by dissection from the fibrous parts, which are then to be fairly divided. Sir Astley Cooper, long before either, recommended that a narrow knife should be passed under the obstacle to extension, and that it should be divided without dividing the skin which covers it. In all cases the finger should be placed in complete extension. If it be a question of a single longitudinal band, Sir A. Cooper's method is unquestionably the best; but, unfortunately, we frequently have bands which send prolongations, and are adherent to the integuments. In appearance Goyraud's method seems faultless; it allows of union by first intention. The cicatrix is linear, and it runs no risk of being destroyed by extension, as is the case when the incision of the skin is transverse. Dupuytren's method has been followed by sub-aponeurotic inflammation of the hand, diffuse suppuration, exfoliation of tendons, and so on; these effects, however, may often be prevented by persevering in the use of cold applications and good position.

BURSÆ MUCOSÆ.

More or less directly connected with the tendinous system are certain mucons

bursæ; and this appears the fitting place for considering the injuries and diseases to which they are subject. We must consider bursæ mucosæ under two points of view, dependent on their situation and connections. We will consider first those which have been scarcely spoken of by anatomists—the subcutaneous. These are found at almost all points where the skin covers parts which move much, but most constantly between the skin and the patella, the trochanter major, the posterior part of the olecranon, the acromion, the front of the thyroid cartilage, sometimes behind the angle of the jaw, and between the skin and the extension surfaces of the metacarpo and metatarso-phalangean articulations, and also that of the first phalanges with the second: but these are most commonly nearly related to the tendons; they exist at the moment of birth, and they increase in size in proportion to the exercise of the parts. Beclard remarked that the acromial one was largely developed in porters; that over the patella is often large in housemaids, and those who pray much.

Wounds.—Wounds of these sacs do not usually give rise to serious accidents, and usually soon heal. When they are *contused* the case is different; indeed, such accidents seem to be the foundation of many of the alterations of which these organs become the seat, and which may be found in the writings of Gooch, Bell, Monro, Cowper, Koch, Herwig, Velpeau, and others. These injuries may cause an effusion of blood, which happens often without pain, and does not attract the patient's attention until the motion of the limb becomes constrained; sometimes it is absorbed, at others it remains apparently stationary, constituting a tumor which, after many years, acquires considerable size. If we open them soon after the injury, we find clots of blood; if it have occurred some time, the capsule is sometimes hard and thick, formed of concentric layers analogous to those of aneurismal tumors. The contained matter is sometimes grey, yellowish, reddish, or blackish; sometimes liquid, at others grumous; sometimes fibrinous. Usually a certain portion of the matter has a synovia-like appearance. Sir B. Brodie has shewn that the *fibrinous flocculi*, which he terms coagulable lymph, whether free and floating, or adherent, often undergo a change which reduces them to the condition of fibrocartilage. Such he believes to be the origin of those seed-like bodies which are occasionally found in considerable number in subcutaneous bursæ; also in those of the tendons, and occasionally in articulations. A species of confirmation of this opinion is furnished by the fact, that the patient usually states that a blow had

been received on the part. When these bodies have acquired a cartilaginous appearance, the fluid in which they float becomes often more like synovia, sometimes glutinous, like the vitreous humour.

Dropsy of subcutaneous bursæ is not unfrequently seen over the patella of persons much given to kneel, and interferes with motion at the part; so it does when seated over the olecranon, it prevents flexion of the forearm; it may occur in other situations, but usually it is less abundant elsewhere than over the patella. It results often from contusion. Camper believed its frequency in front of the knee of the horse resulted from his lying commonly, like other ruminating animals, so that the shoes of the hind feet rub constantly this part of the fore-leg. Though most of these collections may be caused by traumatic agency, yet it would appear that they may be produced by internal causes; and the circumstances vary according to the cause. Thus when produced by external causes, there is a fixed though slight pain from the commencement. The extravasation is not usually manifest for some time after the injury; its increase is slow, and sometimes it remains stationary. On the contrary, when it proceeds from internal causes, it is sometimes suddenly developed, rapidly increases, but rarely acquires great size, and occasionally disappears with as much rapidity as it has been developed. As an example of this I may refer to a case mentioned by Koch, who, in a gouty subject, saw the bursæ over the patella suddenly enlarged; it as suddenly disappeared, and seemed transferred to the knee-joint; from thence it proceeded into that of the popliteus muscle. Cheston mentions a similar case. Asselini mentions a curious case where the affection alternated with abundant glairy vomiting. When the tumor over the patella existed, the health was good; when it disappeared the patient had nausea and vomiting, until an albuminous matter was thrown up. Monro speaks of a case which he believed to be dependent on scrofula.

Treatment.—The treatment of these tumors varies with the causes. When the cause is external, topical applications will often succeed, more particularly when they are rubefacients. Sometimes soap-plaster will suffice; frictions and bandages will often succeed; so will mercurial plaster, and the iodides: when they resist simple means, a succession of blisters will often get rid of them. Of course, we are speaking of the treatment when the disease is not acute. If, in spite of these topical applications, the tumor, instead of diminishing, increases in size, it may be necessary to puncture. When the disease is recent, a single puncture, or incision, at the most depending

point, will usually suffice for its evacuation; and the parietes should be maintained in contact with a bandage. A radical cure very commonly results in a comparatively short time. When the tumor is old, and the parietes thick, it may be necessary to extend the incision through greater space, and fill up the cavity with lint, so as to excite inflammation and adhesion of the parietes. Still they do not always yield even to this method, and it has been proposed to effect a radical cure by dissecting them out. When the tumor is small, they are easily dissected away, with or without previously discharging their contents. When the integuments covering them are altered, the method of Chopart may be employed: open, at the depending part, largely enough to evacuate the contained matter; the incision is then extended circularly, so as to remove the skin with the sac which is connected with it. A wound is thus made, the centre of which is formed by the portion of cyst corresponding to the base of the tumor; this ultimately is thrown off, leaving, under, a dense fibrous tissue. Simple puncture has been commonly employed for simple hygroma: but it often fails; and Monro and Charles Bell advise a seton to be introduced for three or four days. Others recommend, after evacuating, to inject stimulating liquids. In this class we need have no apprehension in doing so; but in those cases to which I specially referred, whether they communicate with those of tendons or not, it is not wise to employ it. Asselini opens with a bistoury rather than a trocar, because the former may make a larger opening, so as to discharge those fibro-cartilaginous bodies of which we have spoken; or, if desirable, it enables him to apply caustic. He has been accustomed to use with success the acid nitrate of mercury. Sometimes the irritation of a probe or the handle of a scalpel is sufficient.

Where the disease seems to be produced by constitutional causes, a clue to treatment may be given. These tumors may become the seat of *inflammation and abscess*. The many causes which we have considered as capable of producing effusion into these sacs may occasion inflammation and abscess. The usual result is such as we observe in serous cavities—the ordinary secretion may be augmented, it may become changed; milky and fibrinous concretions may be formed; it may end in purulent secretion, the cavity is changed into an abscess—these are the consequences of acute inflammation. When chronic, the parietes of the cyst thicken sometimes to the extent of half an inch; in other cases, though they have existed long, no perceptible change of structure happens. Ordinarily, they do not occasion great constitutional disturb-

ance, though I have known great constitutional mischief excited by such disease, between the latissimus dorsi and the angle of the scapula, where the tumor had acquired the size of a child's head: in that case, and in a similar one given by Brodie, death was the consequence.

Although generally chronic, these tumors are now and then acute. There is then a dull, deep-seated pain; the inflammation may extend to neighbouring parts, the skin over them is red, and a fluctuation may be distinguished. This is not easily detected when the tumor is chronic, because the thickening of the parietes gives it the character of a hard compact mass. The contained pus usually finds its way to the surface; but Brodie has seen it burst the lateral walls, and become diffused through the neighbouring tissue, as in a case of diffuse phlegmonous inflammation, and this termination has been oftenest seen over the patella. So long as such tumors remain painful, leeches may be applied, alternated with cold lotions. The cure may be only partial; the disease becoming chronic, the fluid may not be absorbed, and an incision may be necessary for its evacuation, and pressure may be afterwards applied; but this will occasionally fail, and fluid may be discharged for weeks or months. When the abscess is large, Brodie advises a simple puncture to be made, lest serious symptoms may follow. However, he mentions two cases, in one of which the seton, and in the other puncture was employed, which do not favour this opinion: the result was fatal in both.

TENDINOUS BURSÆ.

Those bursæ which form as it were lubricating sheaths for the tendons, and which have been so well described by Jancke, Fourcroy, Monro, Beclard, and Koch, require a separate consideration from those which are subcutaneous. Some of them are confounded either externally with the subcutaneous bursæ, or internally with the synovial capsules of articulations. That which is behind the tendon of the triceps cruralis is often connected with the capsule of the knee-joint: that of the popliteus, it is stated by Fourcroy, always communicates with the same articulation. It is evident that there is a strong analogy between these bursæ and the articular capsules; the membrane lining them is similar, the one and the other are shut sacs, the one and the other secrete a synovial fluid, their connexions are often very intimate, and disease in the one is not unfrequently communicated to the other.

Their adhesion with tendons and bones exposes them to a variety of injuries, consequent upon contusions, fractures, strains, and luxations, and the fluid they contain

is liable to certain alterations. They may be wounded by contusing or sharp bodies, they may be lacerated by the end of a fractured bone, or the violent distension of an articulation. However produced, the injury may be generally detected by the escape of a certain quantity of their fluid with the blood, as well as by the difficulty and pain which are experienced in attempting to move the limb. If the bursa be large, the irritation caused by the wound increases the secretion, and if the capsule be directly connected with a joint it may also become affected. In small bursæ, we often can only judge of their being injured by the situation of the wound. Sometimes the inflammation follows soon after the wound, usually, however, not until some days have elapsed. Monro attributed the accidents to the ingress of air, but in the present day we do not subscribe to this opinion. It is clearly much less to the presence of air, which is not of itself an irritant, than to the motion at the part, that the consecutive accidents should be referred. A little reflection upon the connection of these organs with the tendons will shew the difficulty of preserving immobility: the fatal symptoms which are sometimes observed, as a consequence of opening ganglia of the wrist and hand, support this opinion.

To prevent the development of too much inflammation is therefore the great principle to be kept in view in the treatment of these wounds; all motion at the part should be as far as possible prevented, and if a too intense inflammatory action should be set up, it should be very energetically treated. If we prevent the development of inflammation, these wounds unite soon; but most frequently the capsule adheres to the tendons, and motion is for some time interfered with. If, however, the inflammation should be extended either to a joint or its capsule, much mischief may be the consequence, and at best a considerable loss of motion.

Contusion may be attended with results similar to those we have described in speaking of subcutaneous bursæ; but often the consequences of contusion are serious, principally from their seat and connexions.

Inflammation and Tumor.—What has been said of wounds and contusions of these bursæ has given an idea of the consequences of traumatic inflammation of these organs; they may become inflamed under the influence of internal causes. Sidren has seen them to be violently affected upon the sudden appearance of erysipelas. Koch has seen it follow compression applied for other purposes; he has also seen the knee bursa affected monthly for a considerable time in a young woman who menstruated with difficulty. Lind has seen it often in

the second period of scorbutus. Fourcroy says it is frequent in gout and rheumatism. Brodie thinks it may proceed from an immoderate use of mercury.

The symptoms presented are oblong and more or less large tumor, with a dull pain and diffused heat at the part; the connexions explain the great increase of pain upon motion, and this pain is greater upon extension than flexion, according as the particular capsule is affected. If the tumor be superficial, the skin which covers it is often red and hot, but very frequently it is unchanged; this inflammation much more commonly attacks the bursæ of the knee, the wrist, and the tarsus, than those of other parts. Occasionally they are confounded with disease of the joint, but their seat should prevent that: when the bursa is deep seated, the difficulty of diagnosis is often great, especially when near a joint; it is still further increased when the bursa communicates with a joint.

The disease may be acute or chronic: in the first it is very serious, and often ends in abscess; the adhesions are considerable, the cavity often obliterated, and motion more or less completely abolished. When chronic, similar effects may be produced; they may degenerate under the influence of a seton, for instance, into a fungus or carcinomatous tumor (S. Cooper). According to Koch, the fluid they contain may be transformed into a yellowish or whitish cheesy matter: tumors of this kind, after giving more or less violent pain for some time, ulcerate, and the cure can only be obtained by extirpation with a cutting instrument. Fourcroy thought that the rigidity of a limb after repeated attacks of gout or rheumatism, might depend upon concretions deposited in the synovial capsules of tendons.

These changes, and their connexions with articular capsules, show very clearly a reason why they have been mistaken for white swelling in the joints with which they are connected. This error should not happen if the disease have been seen at an early period; independently of calcareous tubercular and cancerous products, which may be developed in bursæ, they may also contain fibro-cartilaginous bodies, such as I have before described: these are usually not very painful.

When seated at the wrist they are usually divided into two portions, being bound down by the annular ligament; if we compress either we enlarge the other. It is necessary to be careful not to confound these tumors with certain others developed in the neighbourhood of joints. They depend upon the accumulation of synovia, by which the membrane is projected between the ligaments; it is usually easy to distinguish them by their complete dis-

appearance under pressure. In the Edinburgh Medical and Surgical Journal for 1821, is a case in which a ganglion appeared in the course of the radial artery, and was mistaken for aneurism, but fortunately the mistake was soon discovered. I have already stated that usually those tumors were of slow growth, that often they do not acquire great size, nor interfere materially with the functions of the part, that when they are seated on parts subject to constant irritation, they may be inconvenient; if they become large they may be painful, and interfere with motion at the part. They may remain stationary for years; patients have had them for twenty or thirty years without undergoing any manifest change. It is very rarely that they retrograde, or are spontaneously cured.

Treatment.—Many means of treating these tumors have been employed. Solutions of acetate of lead, sulphate of zinc, and other astringents, as well as oil of origanum, have been used, in the hope of dispersing them, and occasionally with success; but it is very rarely that they completely cure though they may diminish the tumor. Alkalines, mercurial frictions, and slight compression, have been used with occasional success, but have often failed. Compression is sometimes made with the thumb, sometimes with a piece of lead, a copper or silver coin, associated or not with friction; friction, however, must not be carried so far as to occasion much irritation at the part, for when much irritated they have been known to degenerate into fungous growths. Pressure violently and instantaneously made, is sometimes employed; for instance, a penny is placed upon the tumor, and smartly struck, or instead of that it is struck with a book, or any other flat body. If it give way, a slight noise is heard, the cyst is emptied, and the contents are diffused through the surrounding tissues, and afterwards absorbed; a certain quantity of inflammation is developed in the parietes of the cyst, it is obliterated, and a radical cure is thus obtained. These tumors are, however, sometimes reproduced, and a new operation is necessary. The seton has been passed through these tumors for the purpose of evacuating the fluid and exciting inflammation in the parietes, but this method of treatment is not without danger. I have known a case in which a tumor at the wrist was thus treated, the inflammation it excited extended to the carpal bones, and amputation was necessary. In the Journal de Médecine, vol. 5, is a case where a carcinomatous tumor succeeded to the irritation of the seton. If they resist these different methods of treatment, and become painful or inconvenient,

they should, if possible, be extracted. For this purpose, a longitudinal or crucial incision may be made over them, and the cyst dissected out. You must take care not to open it, otherwise the dissection is difficult: some persons are content to cut away the anterior walls only. If the tumor be not very large we may endeavour to bring the parts together and heal by first intention, but if it be large, it may be better to introduce lint into the wound, and heal by granulations. When seated in the palm of the hand, unless very inconvenient, they should be left alone. Whether opened or incised, very formidable and painful accidents may be the consequence. Still it is not always so. Warner describes two such cases, in which he completed the extirpation: both did well. Gooch describes a similar case, and many others are recorded. Still serious accidents are so frequent, even when a case has ultimately done well, that the reasons for acting should be very pressing. It is also recommended by some surgeons to puncture and empty them, and afterwards to introduce an irritating fluid, capable of exciting inflammation and adhesion. In some cases repeated blistering will succeed, but will often fail; still, in most cases it is worth a trial.

CLINICAL LECTURES,

Delivered in St. Vincent's Hospital,

By J. M. FERRALL, Esq. M.R.I.A.

First Medical Adviser in Ordinary to the Hospital.

Mammary Abscess—Numerous Fistulæ—Circular compression—Cure—Necrosis of four-fifths of the clavicle—Separation of the bone without injury to the limb—Fungus of the antrum—Lymphatic contamination—No visceral taint.

GENTLEMEN,—Amongst the cases discharged this week, the first to which I shall briefly direct your attention is that of a young woman in Joseph's Ward, with enormous enlargement of the breast, and numerous fistulous openings—hectic fever, and great wasting of the frame. A patient in the last stage of phthisis could hardly present a more attenuated appearance than this young person, when entered for admission. The case is one of practical interest, because, although the treatment of mammary abscess generally is discussed in every systematic work, yet this particular condition of the breast, although of frequent occurrence, has not usually been made the subject of special consideration.

Deep-seated Mammary Abscess, with numerous Fistulæ—Cure by circular compression. (Reported by Mr. W. M'Mahon.)

Fanny Fanell, aged 20 years, admitted into Joseph's Ward with the following symptoms:—

The right mamma is enlarged to three or four times the size of the healthy one. It is irregular in shape, very heavy, and presents a number of fistulous openings on every side, freely discharging purulent matter. The integuments immediately surrounding each orifice are marked by a dusky purple tinge, and are depressed below the level of the surrounding skin. The whole breast is exquisitely painful to the touch, and is often the seat of distressing uneasiness and sense of weight.

She is greatly emaciated, very pale, and complains of excessive weakness. Bowels constipated; tongue coated slightly, but moist; pulse 110, small, and feeble. On waking from sleep, she finds herself bathed in perspiration. No cough; no evidence of pulmonary disease.

I may here interrupt the narrative, to remind you of my observation at the time, that here was a case for the treatment of which no rule of practice was established to which I could invariably subscribe. If you consult the systematic works of character, you will be disappointed if you expect to find this case provided for. Mr. Hey is the only author who seems to direct attention to this particular state, but I believe you will meet few ladies who will submit to the operation he describes. In hospital practice, where the patient has great confidence in your humanity, she will submit with extraordinary patience to the process, and under those circumstances I have performed with success, although the hewing up of a diseased breast in all directions is any thing but an object to view with complacency. I could not help feeling, besides, that erysipelas was very likely to succeed to the infliction of numerous wounds, especially in a constitution already reduced below the standard of health. After describing accurately the condition of the mamma which succeeds to deep-seated abscess with various openings, Mr. Hey says, the cure cannot be accomplished unless the course of the sinuses be traced, and each laid open completely, however numerous they may be, or tortuous in their windings through the organ. He insists on this operation as indispensable, and even admits that, by doing it as it should be done, the breast may be "divided into several pieces." The extent to which the organ was incised may be inferred from his saying that, when any portion of the mamma was thus insulated, and rendered pendulous, his remedy was, to "remove it altogether."

This was bold practice, you will say; but, from the character, experience, and singular ability of Mr. Hey, you may be satisfied that it was not lightly undertaken or recommended. If you look into other authors, as Pearson, James, Boyer, Sabatier, &c., you will find that they consider the question of opening the abscess or not, but do not seem to contemplate the degeneration of the openings into intractable fistulæ, wearing out the constitution of the individual. M. Dugès, in his elaborate and excellent memoir in the *Dictionnaire*, is equally unsatisfactory on this point. He discusses all varieties of mastitis with great precision, but not this peculiar condition which so often succeeds to the abscess if deep-seated. Sir Astley Cooper's valuable advice on the treatment of sinuous ulcers is more in point. He recommends (without particular reference to the mammary fistulæ,) injections and pressure. The material of the injection which he seems to prefer is either port wine or tincture of lytta. It is obvious that we could not hope to make any injection follow the tortuous course of so many fistulæ passing in all and even opposite directions through the substance of the breast: Pressure applied in the ordinary way, or antero-posterior pressure, although of great service in sinuous ulcers of less extent and number, had invariably disappointed me when tried in analogous cases to the present. The pressure, however dexterously applied, had the effect of forcing together the parietes of the fistulous canals at some point of their course anterior to their extreme or further end, and thus prevent the exit of the discharge which was secreted by this distant portion of the pyogenic membrane. The consequence was, that a new dépôt was formed, and a fresh attack of feverishness was set up, until it made its way in some direction or other to the surface.

It occurred to me, however, that pressure could be made available, if, by some modification in the mode of applying it, we could imitate the circular compression which so often succeeds when employed on the limbs; and the remarkable prominence of the mamma seemed to favour our design. With this view we proceeded as detailed in the next day's report.

Jan. 16th.—A probe is readily passed to a considerable depth on some of the fistulæ by accommodating the curve of the instrument to the direction of the canals. The orifices are covered with simple dressing or lint. A series of compresses, made of fine tow, are arranged so as to make pressure on the circumference of the breast or round its base; the anterior portion is left free for the discharge. A double-headed

roller is made to pass over the compresses from beneath; the ends are brought up and crossed over to the shoulders, thence across the back, and round again to the breast as before. The circles were repeated several times, so as to make firm pressure, and acting as a sling to support the breast at the same time. She experienced considerable comfort from the support.

The constitutional treatment consists of animal food, and a little wine. Decoction of bark, with aromatic sulphuric acid, three times daily, aperient medicine being previously given.

It would be useless to read the daily reports in this case. An improvement was evident on the second day, both in the bulk of the breast and in the quantity of the discharge, which was very much lessened.

Jan. 21st.—Several of the ulcers are healed; a small spot, about the size of the top of the finger, on the upper surface of the breast, is red, soft, and painful; about a drachm of healthy pus escaped on puncture; the bandage is re-applied as before.

Jan. 26th.—Her general health is remarkably improved. The night sweats have ceased altogether, and she begins to gain flesh. There is very little discharge from the breast, which is greatly diminished in size.

Feb. 5th.—She is gaining strength and colour, sleeps soundly, and has an excellent appetite. The state of the breast is satisfactory. There are only two openings unhealed; and the quantity of discharge is trifling. The pressure is most comfortable to her. The size of the breast is nearly that of the other.

Feb. 21st.—There has been no discharge for several days. The breast is now as small as the other, but is remarkably firm and solid. Her health and flesh are perfectly restored. Discharged.

One great recommendation possessed by this mode of treatment, compared with Mr. Hey's operation, is its entire freedom from pain or danger. The moment the circular compression was effected, the patient declared she felt comfortable, and was relieved from many of the uneasy sensations she endured before. The mamma was effectually suspended and compressed at the same time, and, the anterior surface of the part being exempted, a free exit was allowed to the discharge. As the breast diminished in size, the bandage was made to advance further forward, until its most anterior portion engaged.

The great solidity which remained after the healing of the ulcers, was the inevitable consequence of the extensive hypertrophy and thickening of the cellular tissue, which was the seat as well of the original inflam-

mation as of the purulent deposits, which succeeded each other, until the entire organ was occupied.

The swelling and prominence of the breast was a favourable circumstance in the present case; but I should think the mode of employing pressure, adopted here, could be used in any case requiring it; for the part could be drawn gently forwards by an assistant while the compresses were being adjusted, so as to act only on the circumference or base of the organ. This would seem to be essential to its success; for it is plain, that any pressure made in front would only have the effect of opposing the free discharge from the parts behind.

The next case, amongst those discharged, is one which shows how little constitutional disturbance may be occasioned by the death and exfoliation of a large portion of a bone, possessing such important anatomical relations as the clavicle.

Necrosis of the clavicle—Exfoliation of four-fifths of the bone at its acromial end, without deformity. (Reported by Mr. Howel Seriven.)

Margaret Day, ætat. 15, was admitted into Joseph's Ward with the following symptoms: an oblong ulcer occupied the centre and acromial extremity of the line of the clavicle; about an inch of this end of the bone projected at an angle through this breach, and the remainder of the ulcer presented an unhealthy surface of large pale granulations.

The projecting bone exhibits three or four irregular openings, through which a probe passes into the substance of the clavicle, and, moving freely about, shows the extent to which the cancellous structure has been removed by absorption.

There is very little pain in the part, except when it is examined, or accidentally hurt. The girl's health is good, and the motions of the shoulder are scarcely impeded. There is very little tendency in the scapula to fall forwards, although deprived of its support.

The limb is supported by the clavicle apparatus, which keeps the shoulder from inclining forwards, and the ulcer is dressed with lint.

The history of this case is briefly this:—Two months ago, after a slight hurt in the part, she felt pain, and in a few days swelling and redness appeared. She found great difficulty in using the arm, but was not prevented from going about as usual. The pain increased, and at length a discharge took place; the opening became larger; and the bone was observed to make its appearance three weeks before admission. She thinks it is coming more forward every day.

From this period to that of leaving the hospital (four weeks), the progress was gradual, and accompanied by no remarkable event. The bone was moved occasionally by the hand, in order to favour its separation. The shoulder was supported by the apparatus: Her general health scarcely required attention.

At length the bone was found lying detached under the dressing, and was examined carefully. The sequestrum was four inches and a half in length. It included the acromial articulating extremity entire, denuded of its cartilage, but otherwise unaltered. The articulating surface was as perfect as that of any dried clavicle from which the cartilage merely had been removed. Internal to this point, or nearer the mesial line, the openings before mentioned were observed. Farther on, the bone was smooth, hard, and compact, externally. At the inner extremity of the fragment an irregular worm-eaten appearance was remarked, and the cancellous structure was here completely removed, leaving merely the shell of the bone,

You will remember, gentlemen, that I explained to you, in the first instance, the grounds on which we were justified in leaving the separation of this necrosed bone to the efforts of nature. In the first place, no constitutional disturbance existed; and as the girl had no pressing necessity for severe exertion, the difference of the time so occupied, compared with that which an operation and subsequent healing would have required, was of little importance. In the next place, there was no evidence that any new shell had been formed, in which case the important parts, beneath or behind the clavicle, might be injured or disturbed by any hasty attempt to remove it. The bone was firmly adherent at its inner end on her admission; and you perceive, by examining this specimen, that no traces of absorption are visible in the middle portion of the fragment.

The absence of a new shell of bone, which in ordinary cases, and in other bones, incloses the sequestrum, will, in this case, account for the early separation of the injured portion. If a new formation had taken place, a solid obstacle would have been opposed to the removal of the fragment. It is curious, however, to remark, that although no substitute had been prepared to do the office of the clavicle, yet the motions and even the power of the arm were little if at all impaired. When we recollect that this bone is the point of attachment for many muscles concerned in the movements of the arm and head, we must be struck with the powers of accommodation possessed by living structures, when not too suddenly injured. The clavicle is broken by a fall,

and at once the arm droops helpless, and the point of the shoulder falls forward on the chest. But four-fifths of the bone may be altogether removed by a slower process, and yet neither of these accidents will occur to any remarkable extent. It has even happened that the entire clavicle has exfoliated, or been thrown off by necrosis, without any loss of power of the limb. A case of this kind is recorded in the *Memoirs of the Academy of Surgery*, Paris, a work replete with valuable facts. In the instance there related, a new clavicle was subsequently formed, and the articulations with the sternum and acromion were affected as in the original bone. In our patient, although the part is healed, there is no evidence of bony deposit as yet. The cicatrix has a firm but yielding feel, and the part can be pushed back without any sense of resistance being communicated greater than belongs to a fibrinous or cartilaginous structure. There can be little doubt, however, that, in due time, new bone will be formed to unite with the portion of the old clavicle which remains attached to the sternum, and to articulate with the acromion at its other extremity. The apparatus is still worn, as calculated to maintain the proper distance between the sternum and shoulder, and cause the new bone to occupy the necessary extent. As to deformity, it is really surprising how little flattening is perceptible, and the cicatrix is becoming narrower every day. I have seen the cicatrix of scrofulous ulceration much more remarkable in every way; and there is reason to hope that when new bone is formed behind it, there will be little to attract attention.

The long-expected death of Ford, the poor woman with fungus of the antrum, affords us an opportunity of ascertaining the condition of the principal organs, and of testing the opinion I entertained as to the nature of the lymphatic swelling which existed beneath the jaw. I shall first read a few of the notes of her case, to refresh your recollection of the appearance of the parts during life.

Fungus of the antrum—Lymphatic contamination—No visceral taint. (Reported by Dr. Drought Dickson.)

Catherine Ford, æt. 45, admitted into St. Mary's Ward, Nov. 5, 1838. She states that for several months before her admission she suffered from pain and swelling of the left cheek, with discharge of bloody fluid occasionally from the nostril of that side. The pain resembled toothache, and excited no apprehension in her mind. The swelling was at first attributed to the same cause, and was disregarded until it had acquired a considerable size.

The tumor occupies the entire region of the superior maxillary bone of the left side. The left eye is much more prominent than the right, and on a plane superior to it. The distance between the inner canthus and nose is much greater than on the opposite side, and the usual depression is filled up by the tumor, which here forms a distinct swelling. The canine fossa is entirely obliterated. The left ala nasi is drawn downwards, and considerably elongated. A fungoid mass is beginning to appear in this nostril, and exudes a foetid discharge of a brownish colour and seropurulent appearance. Within the mouth the palate of the left side, and extending even beyond the middle line, is occupied by an irregular bulging mass, covered only by the mucous membrane. The bone has been absorbed, and the swelling affords only the resistance of elasticity. She is much emaciated, and sallow in colour. Her rest is disturbed by the discharge from the nose flowing back into the fauces.

Beneath the jaw-bone, in the digastric space, a lymphatic, enlarged to the size of an almond, is to be felt; it is remarkably hard to the touch, but is moveable: she has no cough.

These were the notes made at the date of her admission. The extent of parts involved, the extensive destruction of the bones in all directions around the morbid growth, together with the exhausted state of the poor woman, seemed to forbid any operative project. But when we considered that a lymphatic gland had already undergone a morbid change, and that its consistence rendered it very probable, that this change was that of schirroma, I gave up all hope from such a proceeding.

The principal changes that occurred within the first month of her residence in the Hospital, were, the further protrusion and displacement of the eye, and the exposure of the fungus in the mouth, by the giving way of the mucous membrane of the palate. The globe of the eye was displaced more and more every week, and gave to the face that peculiarly hideous expression which is observable in these deplorable cases. At length the axis of the eye was altogether directed outwards and upwards, and the organ protruded almost entirely beyond the eyelids. Notwithstanding all this, vision remained perfect, and she could recognise every person around her, when the opposite eye was closed. The double source of foetid discharge which oozed continually now into the nostrils and mouth, became at length her principal source of complaint, for she had for some time suffered very little from the original pain. It appeared, that the pain diminished in proportion to the destruction of the bones and the free expansion of the tumor.

Early in January she complained of pain in the cheek about its middle. The integuments were inflamed, and a circumscribed swelling distinct from that within was formed. A poultice was applied, and after seven or eight days distinct fluctuation was perceptible in its centre. I made a puncture here, and gave exit to about three drachms of healthy pus. A probe passed into the sac of the abscess gave no indication of its communicating with the antrum. It appeared to be in the substance of the cheek itself. I called your attention to this circumstance at the time, for I deemed it worthy of remark, that a healthy abscess should form over a mass of morbid growth, merely as it would seem from the irritation occasioned by its presence at some distance from the cellular tissue in which pus was formed. I reminded you that analogous collections of matter are occasionally observed in the cellular tissue external to a carious joint, without any communication with disease within. This superficial abscess in Ford's case continued to discharge healthy matter for a few days, and then healed.

From this period until that of her death, in the latter end of January, a degree of somnolency was added to her other symptoms. Her utterance was imperfect, and the constant discharge of fetid ichor, a good deal of which passed into her stomach, destroyed all relish for food: she could not be prevailed on to take nourishment, and her emaciation rapidly increased. She died, in fact, like those who sink from organic disease of the stomach, as much from inanition as from the irritation occasioned by the disease.

Necropsy, twelve hours, post mortem.—You had this morning an opportunity of witnessing the result as follows:—

Chest.—The lungs were sound; a few points of adhesion to the costal pleura were observed towards the base of the right lung posteriorly. The heart was small: the walls bore a reasonable proportion to its size in their thickness. There was no valvular disease.

Abdomen.—The liver was of moderate size; its white tissues rather prevailed, but not to any remarkable degree; carefully made sections in different directions failed to discover any deposit or organic change.

The spleen was of the ordinary hue. The stomach distended with air, and containing some remains of her drinks, with a quantity of glairy mucus. The colour of the mucous membrane was perhaps a little darker than usual, but no vascularity of an arborescent character was observed. There was nothing worthy of remark in the intestines, kidneys, or other parts. The diseased mass was removed, and you here observe the extensive destruction of parts

which it occasioned. The osseous boundaries of the antrum are almost completely removed by absorption. The displacement and disorganization of bones and soft parts in the vicinity of the tumor are remarkable. The structure of the fungus is unequal. You see that it is partly fibrous, and that other portions exhibit a homogeneous and almost lardaceous appearance on section. There is no appearance of softening in any part. We shall now proceed to examine the lymphatic gland, which acquired so little additional bulk while under our observation.

You perceive it is remarkably dense, and cuts like fibro-cartilage; it consists of striæ of transparent pearly colour, between which a yellow texture is to be seen. The latter does not seem to be pulpy, but is evidently less consistent than the other.

So far, then, our diagnosis of the structure of this gland is justified. It is decidedly of schirrous character, and although remaining for months with very little increase of growth, I cannot help thinking that if other circumstances had encouraged the performance of an operation, or afforded the least chance of its success, this lymphatic gland, so degenerated, and having taken on the characters of schirroma, would have been excited into activity, and destroyed the poor woman as effectually as the original disease. Considering the extent of the growth at the period of her presenting herself, and that the mouth, nose, and orbit, were involved in the disease, no surgeon of ordinary prudence and humanity could entertain the idea of an operation.

The post-mortem examination, however, concurs with my own previous experience, and that of others with whom I have conversed, in supporting the probability in such cases of the absence of visceral taint. You are aware that in fungoid growths on other situations, the chances of success from operation are greatly lessened by the frequency of similar morbid deposits in the liver or other organs.

Our means of making minute examination or anatomical analysis of such growths, are not yet sufficiently perfect to enable us to decide whether there be any essential difference between the fungus of the antrum of a malignant appearance, and those which are found elsewhere. But the case before us is quite different from the milder tumors which occupy this situation. Even in its earlier stages it threw out a fungoid mass into the nose, bleeding occasionally, exuding a fetid sanies, and accompanied with a visible decline of health. I would not, however, class it with the medullary fungus, although it seems entitled to some place intermediate between it and the fibrous tumor of the antrum. The peculiar structure which you observe in the lymphatic gland would favour this opinion, and

certainly suggest the rule that when such a tumor is discovered in the course of the absorbents, great caution should be used in deciding on interference by operation.

FATAL SPASMODIC AFFECTION OF THROAT.

To the Editor of the Medical Gazette.

SIR,

IF you consider the following case of sufficient interest to deserve a place in your journal, I shall feel obliged by its insertion.—I am, sir,

Your obedient servant,

R. R. CHEYNE.

Berners Street, April 20, 1840.

A gentleman, aged 34 years, of a highly scrofulous diathesis and feeble constitution, which he possessed in common with nearly every member of his family, had been attacked from time to time, both before and after I was first consulted (now about five years since) with low fever, bringing in its train soreness of the throat, with weakness, loss of voice, dry convulsive cough, dyspepsia, violent spasms of the stomach and vomiting, vertigo, discharge from the ears, and deafness. These symptoms (which did not always prevail together,) were usually attributed to catarrh, and lasted sometimes only a few days; at others, a week, or more, leaving, in the intervals of each attack a state of tolerable health. In addition, however, to these more occasional indications of disease, scrofula, in either an active or passive form, prevailed to an intense degree in various parts of the body, and in particular the glands of the neck were enormously enlarged. Extensive suppuration and ulceration in the latter region, as well as in the left foot, took place about three years ago. The discharge from the neck continued during the ensuing two years; that from the foot (depending upon the presence of necrosis,) persisted to the last. It is remarkable that this profuse rejection of scrofulous matter through the channels of external suppuration seemed to have materially increased the general vigour for the entire year preceding the termination of life.

The disease, which issued in my patient's death, commenced as fever of a remittent character and low type, attended by slight soreness of the throat

and hoarse voice, dry cough, spasms of the stomach, and total loss of appetite. There were no physical signs of tubercular deposition in the lungs, but there was very great diminution of the sounds and impulse of the heart.

The above symptoms gradually declined in severity, so that, at the expiration of a week, they had almost disappeared, when suddenly the case assumed a new and very alarming aspect. The sufferer had awoken out of composed sleep in a fit of dyspnoea, which lasted about a minute, and this had recurred a second time in the course of the quarter of an hour which elapsed before I could reach him. His countenance was then anxious; skin bathed in perspiration; pulse sixty, (common to his best health,) and feeble; respiration perfectly tranquil, and deglutition performed with ease. Shortly after my arrival, I had an opportunity of noting the real nature of the spasms. It was evidently seated in the throat, and compelled my patient to make repeated and violent efforts to fill the lungs, each inspiration producing a crowing sound, exactly like what is noticed in the laryngismus stridulus of children. Before I left him, he had fallen into quiet sleep, which was of some hours' duration, and, with the exception of a slight return at the moment of awaking, he remained free from his alarming symptom, until the evening of the next day, when, directly after the act of deglutition, he was suffocated in the midst of the most awful struggles for air.

It is unnecessary to occupy space in the minute description of the treatment pursued in this case. Upon this head it is sufficient to remark, that throughout, the general principle was steadily kept in view, of supporting the strength, as far as this could be done with a due regard to the nature of the symptoms. I am not sure that the operation of laryngotomy could have been performed with propriety in the absence of any permanent embarrassment in respiration, or of any local or constitutional signs of organic disease of the larynx.

Autopsy, 80 hours after death.—Much objection was made to the examination of the body, and then the dissection was confined to the neck. I was assisted by my friend Mr. Forbes.

Externally, the neck appeared crowded and bulky, and was marked,

from ear to ear, by the scars of former ulceration.

Upon reflecting the skin, platysma, and fascia, numerous superficial glands were exposed in the course of the external jugular vein. The superior cervical glands, and a chain prolonged in the course of and beneath the great vessels and nerves of the neck, were some of them of a large size, whilst all of them displayed different steps, in the series of morbid changes, peculiar to scrofula. Many of these glands completely surrounded and adhered to the sheath of the vessels in its entire course; whilst others, more scattered, must have exerted considerable pressure upon the sympathetic, and those branches of the vagus nerve supplying the pharynx, its constrictor, and the structures of the larynx. The glottis and epiglottis were œdematous, the mucous membrane being of a paler tint than natural, and when laid open, throughout the larynx and trachea, was found to be free from ulceration, and altogether healthy.

REMARKS.—The history of this case, and the result of the dissection (limited as it was) illustrate, in a very satisfactory manner, certain points in physiology and pathology. In the first place, I was disposed to think that the œdema of the glottis did not materially impede the act of respiration. I am, however, aware that very slight obstruction, in this situation, might occasion fatal spasm; but, then, an inflamed or ulcerated state of the mucous membrane almost invariably co-exists as a source of irritation. The interruption to the venous circulation, which must have arisen from the presence of such a mass of enlarged glands, in the vicinity of the glottis, or the violent contraction of the parts, which had taken place just before the death of my patient, may certainly have produced the serous effusion.

It is well known that pressure upon the pharynx or larynx by means of any tumor may excite spasms of those organs, simply from irritation of the sensitive nerves of the mucous membrane, and the reflected influence of the motor nerves; and, also, that *direct* compression or irritation of nerves induce various, more or less important, derangements of their functions. In my friend Dr. W. Baly's abstract of Dr. J. Reid's experiments upon the eighth pair of nerves, it is stated, first, that, on

irritating the pharyngeal branch of the vagus, rapid and vigorous movements of all the pharyngeal muscles and upper part of the œsophagus follow; secondly, that irritation of the inferior laryngeal nerve produces strong movements of the arytenoid cartilages, while irritation of the superior laryngeal nerve (by galvanism) gave rise to no action in any of the muscles attached to the arytenoid cartilages, but merely to contraction of the crico-thyroid muscle; thirdly, that division of the recurrent nerves put an end to the motions of the glottis, but that the sensibility of the mucous membrane remains; that division of the superior laryngeal nerve leaves the movements of the glottis unaffected, but deprives it of its sensibility: fourthly, that irritation of the trunk of the vagus excited motions of the œsophagus which extended over the cardiac portion of the stomach*.

Müller remarks, "That the vagus affords sensitive influence to the organs of voice and respiration, the pharynx, œsophagus, and stomach;" and that "from irritation of the branches of this nerve, which is propagated to the brain, a number of spasmodic movements of the organs of respiration, as coughing, vomiting, &c. are produced." He goes on to say, "that a consideration of all the different results, obtained after tying or dividing the nervus vagus, leads to the inference that death arises from the concurrence of different circumstances, which, at last, produce suffocation. They are the following:—first, incomplete paralysis of the muscles of the glottis; second, exudations in the lungs; third, change in the chemical process going on in the lungs; fourth, coagulation of the blood in the vessels, as observed by Mayer†."

It seems to me, that the pathology of the case I have above detailed offers very beautiful evidence in support of the views of experimental physiology. It is, indeed, difficult to explain many of the remarkable symptoms from which my patient had been so long a sufferer, (and particularly those which preceded his death,) otherwise than upon the supposition that they sprung from direct or indirect irritation of the sympathetic and vagus nerves. And I may add, that probably most of those obstinate

* Müller's Physiology, by Baly.

† Ibid.

spasmodic affections of the organs of respiration and digestion, which so frequently occur in children and adults of a scrofulous habit, owe their origin to a similar cause. The troublesome dyspepsia, also, to which such individuals are extremely subject, perhaps may depend upon the existence of some obstacle to the passage of nervous influence, and the consequent diminution of secretion.

In connection with the above remarks, it is instructive to observe how continually, in the irritable constitutions of children, the sensitive influence of the vagus, and its organic actions, derived from the sympathetic nerve, are disturbed, so as to produce disease which simulates inflammation, but which is purely of a spasmodic nature. For example, a child, said to have been in good health until the moment of the attack, (although the bowels have, in all probability, been torpid, and the motions deficient in bile for some time previously) is suddenly seized with wheezing, dyspnoea, and cough, the pulse being rapid, the skin hot, and the face flushed. This very common sympathetic and spasmodic affection is too often treated as inflammation of the lungs, to which, indeed, it bears a strong resemblance; but it goes off as rapidly as it came on, and really requires nothing more than one or two emetics, and an active mercurial purgative. Much the same condition exists (requiring similar treatment) in many of the cases, called asthma, occurring in adults, and in which the attack may often be distinctly referred to some irritation of the stomach, excited by error in the quantity or quality of the diet. Experience, however, teaches us that irritation or congestion of the brain itself mostly co-exists with, if it do not precede, derangement of the organic functions. Thus, in infantile remittent fever, (the phenomena attending which well illustrate the dependence of nutrition and secretion upon the nervous system,) the paroxysm is marked by an extremely rapid pulse, a flushed face, suffused eyes, hot skin, and drowsiness; or, in other words, by evident cerebral irritation. There are immediately established sympathetic affections of the lungs, stomach, and liver, viz., increased secretion of mucus in the air tubes, with cough, and more or less paralysis of the stomach and liver, as indicated by a total want of appetite, and costiveness.

If food be taken, it is generally vomited in an undigested state, and the motions are chalk-like, or clay-coloured, from deficiency of bile. As the disease advances, delirium, screaming, strabismus, &c. point out a more acute affection of the brain; and, as might be expected, this state is productive of still greater disturbance of the functions of the nerves supplying the organs of respiration and digestion, so that, after a few weeks, if soreness does not follow the treatment, the little patient dies from absolute exhaustion. It is of little consequence to determine whether the brain has been primarily or secondarily affected, inasmuch as the appropriate remedy is adapted for either view of the case. This remedy I believe to be calomel, continued perseveringly in small doses, at regular intervals, until the local and general symptoms give way.

In conclusion, I would observe that numerous cases are daily met with in the practice of medicine, which appear under the forms of obstinate functional disorders of the organs of respiration and digestion, combined with imperfect nutrition and secretion, in which, after the failure of ordinary measures, it would, no doubt, be of much advantage to devote a more exclusive attention to the nervous centres.

NOTES ON THE EFFECTS OF IODINE,

AS A REMEDY FOR CUTANEOUS ERUPTIONS.

BY DR. KENNEDY,

Of Ashby de-la-Zouch.

(For the *Medical Gazette*.)

IN many cases, most of them old both in standing and treatment, I have found the iodine a most efficacious remedy for those disorders of the excrement system which affect the skin, especially the vesicular and pustulous kinds. Such being my experience, I feel desirous of having the practice tested under the observation of others, with a view to its being rendered more extensively useful.

Sometimes, in mild cases and untainted constitutions, the iodine may be used internally without assistance; but, on all occasions, its external application requires to be accompanied by a course of medicines capable of acting on the skin, bowels, and kidneys, so as to improve their functions by its salutary effects.

As the nosology of these diseases must be familiarly known, it will be sufficient here to denote in a simple enumeration such of them as have yielded to the iodine under my instructions. These, then, in Dr. Good's nomenclature, are—

Exormia lichen.—For such of the lichenous rashes as prevail in this climate, the iodine should be exhibited internally with alteratives; and externally, in a tepid or warm solution.

Ex. prurigo.—For the pruriginous rashes, the external iodinated applications should possess considerable energy, and be often applied; with the internal remedies, a proportion of henbane, hemlock, or other anodyne, may be combined.

Lepidosis pityriasis.—For the dandriffs and branny scales, the iodinated lotions must be regulated in strength according to the patient's age: the solution of magnesia, with carminatives, will conduce to their efficiency.

Lep psoriasis.—The dry scales require frequent ablutions with the remedy in a vigorous form, and its powers may be assisted by a general warm bath in saline mineral water, artificially strengthened with an iodinated impregnation.

Ecphlysis pompholyx.—The water-blebs, particularly when large, yield more readily when friction and generous tonics accompany the topical applications.

Ecph. herpes.—For shingles, ring-worm, and the tettery vesicles, the iodine, both in solution and ointment, applied actively, will be materially assisted by the occasional interchange of poultices and emollient embrocations, for the removal of crusts.

Ecph. rhyppia.—Blains are best prevented from degenerating into sordid or gangrenous ulcers by frequent gentle excitement of the parts with iodine, and this must be carefully supported by an energetic constitutional treatment.

Ecph. eczema.—Heat-spots, with their clustering vesicles, resist the iodine less obstinately when it is attended by a course of cooling alteratives, and a weekly warm bath in mineral water, wherein the chlorides predominate.

Ecpyesis impetigo.—All the running scalls have yielded to the iodinated treatment, and this proves most successful when the external applications are

very frequent, but so modified as to stimulate the pustules without inducing excessive irritation; in these affections, the constitutional alterants should be as energetic as the system will admit.

Ecpy. porrigo.—The various scabby scalls require the strongest topical applications of iodine freely and assiduously repeated, with such a systematic internal use of the medicine as to promote its diffusion through the circulating fluids; for ascertaining this effect, the urine may be submitted to suitable tests.

Ecpy. ecthyma.—For the papulous scalls, the local applications must be adapted to the irritability of the system; but the iodine may be administered in free combination with tonic alteratives, so as to purify and invigorate the constitution.

Ecpy. scabies.—For the itches, in all their filthy forms, the iodine will be found an active and almost certain specific; it kills the parasite which originates the disease: the milder cases will yield to an iodinated lotion frequently applied, at the temperature most agreeable to the patient's feelings.

Malis, the cutaneous "invermination."—For the most troublesome kind of pedicular disease, the undiluted tincture of iodine constitutes a powerful and certain, but not disagreeable remedy; it should be continued for some time after the animacules have disappeared, so as to insure the destruction of their eggs.

Four forms of iodinated medicine—*Tinctura Iodini Composita*, *Unguentum Iodini Compositum*, *Potassii Iodidum*, and *Liquor Potassii Compositus*—were employed in treating the cutaneous affections here specified; the two former, as external applications; the two latter, internally as alteratives. The tincture may be applied to the worst parts in succession, in a concentrated or diluted state, by anointing them with it on a feather or hair-pencil thrice in the day, or oftener, as indicated; and at bed-time they should be carefully smeared with the ointment, its proportion being regulated by their tenderness and extent. In the morning there will be advantage in gently washing them with tepid water and soap, before pencilling them with the tincture; and at night, about twice in the week, they may be covered over the ointment, with a common emollient poultice; this removes the incrustations on their becoming firm, and soothes the

sores when they happen to be congested and painful.

For an alterative medicine, the iodide of potassium or its compound solution may be administered twice in the day, in a bitter or other vehicle, with the aperients always at night. With these, the disulphate of quina or some preparation of iron, and occasionally, though seldom, the blue pill or calomel, with ipecacuan or other diaphoretic, may be exhibited in different combinations. At this place, and without impropriety, the question may be raised as regards the properties and effects here ascribed to iodinated medicine; may they not belong more properly to the other active remedies simultaneously administered? Without the iodine, however, these do not prove equally efficient; and, moreover, their results are uncertain, generally imperfect, often unprofitable, even when associated with the usual topical applications.

There is this advantage in the exhibition of iodine for the before-mentioned diseases, that, when the constitution remains sound or little impaired, with the alimentary system healthy, a free external application of the medicine will effect a cure, without assistance from other remedies. Although injurious effects have sometimes, though not often, supervened during the administration of iodine, yet, on such occasions, the inconvenience or suffering should rather be ascribed to an indiscriminate use of the drug, and to the neglect of guarding patients from the liabilities of peculiar constitutions. Iodinated medicines have been liberally prescribed by me, in hundreds of cases; nevertheless, not more than one instance of unfavourable symptoms has occurred, and these happened to a young hysterical female while being treated for a bronchocele or "full neck." She was naturally endowed with much irritability of the nervous system; and this, by her mismanagement of the remedies, was rendered the source of distressing muscular jerkings in the heart, face, and extremities.

Except on very delicate surfaces, or where the skin is abraded, the iodine excites only a transient smarting, and this very seldom becomes severe: should the pain grow intense, as a casual exception, the parts should be carefully fomented with warm water, which will mitigate the symptoms, by diluting or

partially removing the medicine. Usually the iodine produces dry scales or crusts, without corrosion of textures. On inspecting the parts subjected to its action, the observer will perceive, with the assistance of his microscope, the impossibility of their being able to propagate the disease by contagion. If their morbid state is caused by a palpable substance, this will be destroyed; if it is an impalpable essence, its evolution will be counteracted by the topical iodinated applications.

When ring-worm, the scalls, and other "outbreaks" on the head, are being treated, the hair should be constantly kept as short as possible, by cutting it frequently with thin-bladed scissors: in many respects, this method is preferable to that of shaving the parts with a razor. Hair and organic textures get a yellow tinge from the action of iodine; but after its discontinuance, they soon and completely recover their natural colour.

There is good reason, from extensive observation and analogy, for concluding that, under suitable modifications, the iodine will prove an effectual remedy for nearly all the cutaneous disorders, particularly those which derive their local source and support from animalcular depredations. At the same time, every attention is essentially requisite, that proper internal appliances be instituted, with the twofold object of preventing a recession of the superficial malady to a deep-seated structure, and of sustaining the functions of vital organs in a state of vigorous activity.

Without adducing evidence in support of the statement, on the present occasion, my belief is, that most of the vesicular and pustulous eruptions on the skin, are produced and propagated by the "invermination" and incubation of animacules, derived from the atmosphere and disseminated by contagion. My suggestion is, that patience and attentive observation be exercised in endeavouring, with iodinated medicine, to secure the extirpation of these parasites and their eggs from their burrows in the cutaneous structure; and my hope is, that, at no distant period, these detestable intruders will be detected by the ingenuity and perseverance of pathologists experienced in the processes of microscopical investigation.

April 9th, 1840.

ACETATE OF LEAD IN BRONCHITIS.

By WM. HENDERSON, M.D.

Fellow of the Royal College of Physicians, and
Lecturer on Practice of Medicine, Edinburgh.[For the *London Medical Gazette*.]

SEVERAL years ago, having had repeatedly occasion to regret the inefficacy of the medicines commonly used in bronchitis, when the object in view was the restraining of a too abundant secretion, by which the bronchial tubes were loaded, and the respiration greatly embarrassed, I was glad to avail myself of a notice contained in the *MEDICAL GAZETTE* of 1833, and extracted from *Rust's Magazine*, in which the virtues of the acetate of lead were represented as specially adapted to the circumstance in question. The cases in which I had had the greatest reason to feel the want of a remedy which could restrain the secretion from the bronchial membrane, were the bronchitic disorders of children, occurring in connection with measles and with whooping-cough; and it was in cases of this kind that I subsequently had the satisfaction of first witnessing the beneficial operation of the acetate of lead in inflammation of the bronchial mucous membrane.

After a careful investigation of the powers of this remedy, continued for several years, and based on an ample compass both of personal observation and the reported experience of several practitioners to whom I recommended the use of it, I feel warranted in stating my conviction that the acetate of lead is a remedy by far the most worthy of reliance in bronchitis attended with profuse secretion. The useful agency of this preparation is not confined to the bronchitis of measles and whooping-cough, but is equally observable in the simple bronchitis, and in that which so often occurs as a complication of continued fever. In whatever class of cases I have prescribed it, its administration has been limited to that period of the bronchitis in which the evidences of abundant secretion were apparent; and those evidences have formed the only guides which I have found it requisite to follow in the first exhibition of the remedy, and in regulating the bulk and frequency of the doses. The stage or duration of the disease does not require to be regarded in prescribing the ace-

tate; and, though it exerts a signal and most salutary influence on the secretion of chronic mucous catarrhs, it has always appeared to me that its chief value consists in the rapidity of its operation in such acute cases as are characterized by copious secretion, whether of the muco-purulent appearance or not, whereby the respiration is impeded, and suffocation is threatened.

In acute bronchitis, diverse effects have been observed to succeed the use of the lead. In some instances a very speedy and entire removal of the rattle has ensued, without the pulse having been lessened in frequency, or the respiratory acts materially altered from their previous condition. In such I have been accustomed to omit the lead, and to recur to the antimony, ipecacuan, and calomel, or to whatever remedy had been previously used. In a second class of cases, the rattles have merely undergone a considerable diminution, while the other symptoms have continued nearly or altogether as before. In those I have found it of great advantage to alternate, with the exhibition of the acetate of lead, either the antimony or calomel and ipecacuan. In a third class, no material change of any kind has followed the use of the lead for several days. The cases of this class, for the most part, consisted of whooping-cough, with intense general bronchitis; and in the treatment of them, the acetate has been given in much larger quantity, and continued longer than in the others. I have repeatedly ascertained, in cases of this kind, that though the number of rattles, and the apparent amount of the secretion, seemed but little reduced from the state which they had presented on the lead being first administered, a marked change for the worse has followed the omission of it. In this class of cases, the doses of lead have been usually alternated with those of some common remedy; yet the latter have been frequently omitted, unless some indication of pneumonia existed, without apparent disadvantage. In a fourth class, composed mostly of cases in which the secretion appeared, from its extreme abundance, to be the principal cause of the more harassing symptoms—to wit, the hurried acts of respiration, dyspnoea, and consequent restlessness, &c.—the decrease in the number of the rattles, more especially the larger mucous rattles, which has commonly soon

followed the administration of the lead, has been very generally accompanied by a commensurate decrease in the other important symptoms. In not a few instances of feeble children, labouring under acute general bronchitis with copious secretion, have the effects of the acetate been observed, by myself and others, so promptly and decidedly manifested as to excite no little surprise, and to alter the prognosis speedily, from a very gloomy to a very cheerful aspect.

The dose in which this medicine may be given must vary with the exigencies of the case and the age of the patient; though the latter particular is of less importance. Indeed I have hitherto found occasion to give it in much larger quantity to children than to adults, owing to the much greater frequency and severity of acute bronchitis in the former. The quantity taken in twenty-four hours by an adult has not exceeded twelve grains, in doses of from one to three grains. The cases of acute bronchitis in the adult in which I have used the lead, have been mostly complications of continued fever. Along with the lead there were usually given a few grains of the compound powder of ipecacuan; sometimes with the addition of the powdered squill. The common doses to children have been, according to the severity of the case, a quarter, half, or whole grain, from to eight or ten times a day. In one very severe, and at one time almost hopeless case, so much as four scruples were swallowed within ten days. The child was six years old, and the disease intense general bronchitis, supervening on whooping-cough. No such bad effects succeeded as are too commonly dreaded from them medicinal use of the acetate of lead, though the gums corresponding to the lower incisors exhibited the blue tint pointed out by Dr. Burton, on the fifteenth day from the commencement of the use of the lead, and it is probable that it existed previously to that date, though unobserved. Nor have I hitherto witnessed in any case the dreaded effects of the lead, not even to the extent of causing constipation.

In the chronic mucous and mucopurulent bronchitis, there is no remedy, I firmly believe, (and I have tried a great many) that possesses nearly the controlling power over the quantity of the secretion, which is displayed by the acetate of lead. I usually give it in a

pill containing one or two grains, along with some extract of hyoscyamus and a grain of squill, three or four times a-day.

I have thought it of consequence to let the experience which I have had of the properties of this remedy in bronchitis, be known; because it appears that they have nearly or entirely escaped the notice of the generality of practitioners. The only suggestions with which I am acquainted, of the utility of the acetate of lead in bronchial inflammations, besides that to which I have referred, are by Sauvages, in his *Nosologia Methodica*; by Dr. Reece, in the fifteenth volume of the *Medical and Chirurgical Review* (both of whom recommend it merely to relieve irritation in whooping-cough); and by Dr. Stokes, in his first volume on *Diseases of the Chest*, who conjectures that it might be of advantage in certain forms of chronic bronchitis.

ON THE TREATMENT OF SPRAINS BY STARCHED BANDAGES.

To the Editor of the Medical Gazette.

SIR,

I AM induced to send you the following observations on the treatment of sprains with starched bandages, in consequence of the success which I have observed to follow that method of cure.

Accidents of this kind are sometimes both extremely tedious and annoying to the medical attendant, not only from the pain which the patient has been obliged to endure, but also from the vexation which absence from business and confinement to the house produce. The plan of treatment which we recommend is quite similar to that used and recommended by MM. Larrey and Lentin, in fractures of the extremities, and the advantages which accrue from it, are chiefly in enabling the patient to go sooner about and attend to his usual occupation, without at all retarding the cure. If the contained observations should meet your approbation, I shall feel obliged by your inserting them in your excellent and useful periodical.

I have the honour to be, sir,

Your most obedient servant,

ROBERT PATERSON, M.D.

Physician to the Leith Dispensary,
&c. &c. &c.

North Leith, Apr 17, 1840.

Sprains, as is well known, are generally produced by great force applied to a joint, or by a smaller degree of force awkwardly applied when the muscles of the limb are unprepared for it; the result of which is, that the ligaments, tendons, and their sheaths, which surround the joint, are violently stretched, and in some cases torn. After a short time, sometimes almost immediately, great tumefaction and stiffness of the affected joint takes place, from effusion of blood and serous fluid. Such cases are of very common occurrence, and are familiar to every practitioner. They are universally classed among the most tedious and troublesome cases which fall under the care of the surgeon. The treatment adopted by different practitioners is extremely various; some apply leeches, others cold evaporating lotions, others warm fomentations, while some trust to stimulating frictions, and perhaps it is a general fault among medical men to resort too much to one method of cure, to the exclusion of other means. The treatment of such cases which we have been in the habit of following for some time past, has certainly been attended with more decided success than any which had formerly come under our notice. Not only is the patient saved much suffering, but is enabled sooner to attend to his duties, and to take that exercise in the open air, which is so congenial to health and speedy convalescence. By means of the following treatment, our patients may, (even after having suffered a very severe sprain), be enabled to go about their usual avocations in six or eight days. Upon being called to a case where a sprain has occurred, the extremity must be elevated and kept at rest. Cold evaporating lotions, or warm fomentations, are to be applied according as the one or other is more agreeable to the patient's feelings, and also according as we see the case immediately after the injury, or some time after its occurrence; in the latter case, warm fomentations are always most beneficial, and most relished by the patient. It may be necessary also to use local blood-letting, when symptoms of inflammatory action make their appearance; this, however, we believe will seldom if ever be required if the accident is seen at an early period. After the swelling around the joint and in the course of the tendons has nearly subsided, under

the use of such or similar applications, the starched bandages, first recommended by M. Larrey, and afterwards by Dr. Lentin, of Brussels, in fractures of the extremities, are to be applied. In the employment of these bandages, it is of the greatest consequence not to apply them so long as the limb continues very painful or much swollen; at the same time, it does not do to wait until the pain has altogether subsided, or the swelling entirely fallen, for this is seldom accomplished until a considerable time has elapsed, and until a bandage is applied.

In applying the bandage we always follow the plan of Dr. Lentin, of Brussels*. Two or three pieces of broad stout cloth, well covered with starch, are to be folded and applied on each side of the limb, across the affected joint. One or two rollers also well starched are then applied over these, not very tight, but still of sufficient tightness to give gentle compression to the whole of that portion of the limb. These dry readily in twenty-four or thirty-six hours, on exposure to the air. It has been recommended to facilitate the drying of the starch, by passing a heated smoothing iron over the bandages, but we have found that this has a tendency to render the limb more painful, and to increase the inflammatory action in the part.

The size and length of the bandages are always to be proportioned to the joint over which they are to be applied.

Sprains most commonly occur in the wrist and ankle-joints, and then it is advisable to use bandages which will reach respectively from the middle of the fore-arm to the palm of the hand, and from the middle of the leg to the digito-tarsal articulation.

The advantages resulting from this plan of treating sprains are obvious: it exerts a comfortable and most beneficial degree of pressure upon the injured parts, while the moisture of the starched bandages acts as a temporary fomentation, and when they dry, the stiffness which they acquire, and the continued and regular pressure which they exert upon every point to which they are applied, completely prevent every kind of motion of the injured joint, even al-

* M. Larrey, junior, sur le traitement des fractures par l'appareil immobile de Dr. Lentin, &c. &c.

though the patient may be using the rest of his body very actively.

It may be well to mention, however, that it is sometimes necessary to apply a couple of strong pasteboard splints on each side of the injured joint, until the bandages dry.

In the course of the last six or eight months, during which time we have had occasion to treat a considerable number of severe sprains of the wrist and ankle-joint, we have been well satisfied with the progress which they made under the plan of treatment just detailed.

The two following cases have been selected not only on account of the severity of the injury, but also because of the speedy cure which was effected; and it is hoped they will serve sufficiently to illustrate the subject.

Two men, one on the occasion of the Queen's marriage, in cleaning the windows of a house in the third flat, fell, and, besides receiving other bruises and wounds, severely sprained his ankle joint. The other fell through the flooring of a distillery loft, the beams of which had been charred by the kiln beneath, and also, (in addition to other bruises) received a severe sprain of the ankle joint. Both were treated in the manner we have described: the one was enabled to go about with the assistance of a stick in the course of five or six days from the receipt of the injury, and to return to his work in the course of as many days more; the convalescence of the other case was a little longer delayed, solely on account of the bruises he had sustained.

PTYALISM FROM THE MEDICINAL USE OF ARSENIC.

To the Editor of the Medical Gazette.

SIR,

If the accompanying case is worth a corner in your useful record of medical facts, I beg to place it at your disposal.

I am, sir,

Your obedient servant,

GEORGE JONES.

St. Leonard's-on Sea, April 28, 1840.

In consequence of a paper by Mr. Hunt, reported at p. 77, vol. 2, of the MEDICAL GAZETTE, I have occasionally prescribed arsenic in cases of mœnor-

rhagia, and with manifest advantage. The following very decided cure from its use was attended with symptoms which I have no recollection to have seen recorded as resulting from the medicinal use of this mineral, and may, therefore, not be uninteresting to your readers.

Mrs. L., æt. 46, stout in person, and of a florid complexion, says, that "for several months she has not been free from the menstrual evacuation, and that now she is almost drained by it."

℞ Liq. Arsenic, ʒij.; Sp. Lav. C. ʒi. M.
Capt. gtt. vij. ter quotidie ex aqua.

The case was nearly lost sight of for a month, during which she had continued to take the drops: at the end of that time, she applied to me on account of what, on a cursory view, led me to imagine was the effect of mercury—extreme siccator of breath, superficial ulceration of the gums and fauces generally, with increased salivary secretion. She then made the following statement:—After the drops had been taken, with little or no inconvenience, for a fortnight, the mœnorrhagia gradually subsided into an offensive discharge of a muco-purulent character, which has now left her altogether; at the same time the secretion of saliva increased, and her mouth became slightly affected. Not suspecting that the soreness could be referrible to the medicine, she continued its use as long as it lasted. Her mouth continuing to get worse, she then made application for further advice. In about a week or ten days she became convalescent, under the following treatment.

℞ Magnes. Sulph. ʒi.; Acid. Sulph. D. ʒi.; Aquæ, ʒvj. M. partitis vicibus, sumend. donec respond. alvus.

℞ Sol. Sodæ Chlor. ʒi. Aquæ, ʒxi.; M. ft. Lotio pro ore sæpe utend.

℞ Argent. Nitrat. gr. iss. Acid. Nitrici, gtt. v. Aquæ Distill. ʒij. M. Capt. coch. parvum, ex Aqua 4tis horis.

POPLITEAL ANEURISM.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider a report of the following case worthy a place in your widely circulating journal, I should be obliged to you to insert it.—I am, sir,

Your obedient servant,

HENRY BULLOCK.

Uxbridge, April 30, 1840.

William Flanders, a policeman, aged 41 years, the subject of popliteal aneurism of six months standing, was admitted a patient of the Uxbridge Dispensary on the 30th of December, 1839. The tumor was of immense size, filling the popliteal space, the circumscribed aneurismal sac alone being as large as a fetal head, besides the general swelling of neighbouring parts. The leg was œdematous, and flexed nearly at a right angle, and the veins were varicose, while no pulsation could be detected either in the posterior or anterior tibial artery. Under these untoward circumstances, it was thought by several surgeons questionable whether, the femoral artery being secured, the collateral circulation would be adequate to the support of the limb, from the probable obstruction of the anastomosing branches of the profunda artery. Notwithstanding the success of the ligature was thus rendered doubtful, I was anxious to make trial of this operation, presuming that the prospect of the man's recovery, even after amputation, in the event of our being driven to that extremity, would not have been materially lessened by the application of the ligature. The operation was therefore performed about four inches below Poupart's ligament. It occurred to me, that the aneurismal needle, unarmed, might be insinuated around the artery with greater facility, and less detachment of the artery from its sheath, than armed with the ligature, and nothing can be more practicable than to pass the silk through the eye of the needle whilst beneath the artery. This modification of the ordinary operation I thought desirable, since the effect of the ligature depends so essentially upon the non disturbance of surrounding parts. The ligature being tied, all pulsation ceased, and the tumor became flaccid and diminished. Without burdening the case with details, I will conclude by stating, that the man progressed uniformly well, the wound had healed by the fifth day, leaving space only for the ligature, which separated on the twenty-fourth day, and at the expiration of three months, his heel having reached the ground, he could walk tolerably well.

There is still an induration of the popliteal space, about the size of a pigeon's egg, but which is evidently subsiding. Notwithstanding the limb is perfectly well nourished, and at the na-

tural temperature, yet there is no perceptible pulsation either in the anterior or posterior tibial artery.

OBSERVATIONS
ON THE CAVERNOUS SINUS,
WITH THE DESCRIPTION OF AN ADDITIONAL
SINUS, OCCASIONALLY FOUND IN ITS
EXTERNAL WALL.

BY JAMES MERCER, M.D.,
Demonstrator in the School of Anatomy, 4, Surgeons' Square, Edinburgh.

[For the *London Medical Gazette*.]

ANATOMISTS usually divide the sinuses of the cranial cavity into two classes; the first, embracing all those which are formed in the folds of the dura mater suspended within the cavity, and which return nearly the whole of the blood circulated in the substance of the cerebrum and cerebellum, and in the meninges of the upper part of the cavity and the folds themselves; and the second, including all those which are formed in the membrane lining the different fossæ in the base of the cranium, and which return the blood circulated in the contents of the orbital cavities, in the membranes of the base of the skull, as well as a considerable portion of that which has been circulated in the inferior surfaces of the anterior and middle lobes of the cerebrum.

Each of these classes of sinuses has one which is the common receptacle, and forms the centre of communication with the whole of the sinuses of that class.

To those of the first class, we find the large cavity called the torcular herophili forming this centre of communication to the other sinuses belonging to this class; and to the second, the large regular cavities placed in the membrane covering the side of the body of the sphenoid bone, performs the same offices. Connected with the latter sinuses, there is a circumstance which we have observed several times of late, and which we have not been able to find taken notice of by any preceding anatomists.

Some time ago, whilst demonstrating these different sinuses to the pupils, in the Anatomical Rooms, we observed a very large and distinct sinus, situated in the external wall of the cavernous sinus, and having no connection with the latter cavity. Having several times

repeated these observations since that period, and with the same results in almost every instance, and not finding the occurrence of such a state of parts taken notice of by our best authorities on the subject, we have been induced to draw up the following observations regarding its situation and formation:—

As the situation of this sinus, however, is so intimately connected with the cavernous, and as its description cannot be given without frequent and repeated reference to it, we deem it necessary, in the first place, to allude shortly to the situation and formation of the cavernous sinus; and secondly, to describe the situation and formation of this additional sinus, to which our present observations more particularly belong.

The large irregular cavity of the cavernous sinus, is placed, as we have stated, along the side of the body of the sphenoid bone, and is principally formed by the expansion of the ophthalmic sinus between the irregular splitting of the dura mater, extending between the anterior and posterior clinoid processes.

Anteriorly, it lies immediately behind the foramen lacerum anterius, at its internal extremity or base, and under cover of the anterior clinoid process; opening into it in this situation, we find the large ophthalmic sinus, which leaves the orbital and enters the cranial cavity by the above-named fissure.

Posteriorly, it is formed by the extreme point of the tentorium cerebelli and the posterior clinoid process; and, extending between the inferior surface of this process and the apex of the petrous portion of the temporal bone, we have generally found a very thick, rounded and distinct band of fibres, dividing the posterior wall of the sinus into two parts, and converting the concavity beneath the posterior clinoid process into a distinct foramen. The external of these divisions leads directly outwards, and becomes the superior petrosal sinus; whilst the internal runs downwards and a little outwards, and becomes the inferior petrosal sinus.

Superiorly, it is formed by the extension of the dura mater from the anterior to the posterior clinoid process.

Inferiorly, it rests upon the apex of the petrous portion of the temporal bone, the cartilage filling up the foramen lacerum medium, and the superior opening of the carotid canal, and extending as far anteriorly as the base of the fora-

men lacerum anterius. From these different parts, it is separated by a thin layer of dura mater, and leading downwards from it, through the foramen lacerum medium, we find a tubular prolongation of the dura mater with the lining membrane of the sinus, and this, ultimately, becomes the superior pharyngeal vein.

Its internal wall is formed partly by the side of the body of the sphenoid bone, and partly by the dura mater, which extends between the anterior and posterior walls of the sella turcica. This latter part of the internal wall is rendered concave by the body of the pituitary gland, before and behind which we generally find a large sinus, passing across the sella turcica to the sinus of the opposite side, and thereby forming what is usually denominated the circle of Ridley.

The external wall of the sinus is the greatest in point of extent of surface, and in the density of the membrane which forms it. It extends, superiorly, from the surfaces of the clinoid processes; inferiorly, to the apex of the petrous portion of the temporal and the great wing of the sphenoid bones. Anteriorly, it stretches to the base of the foramen lacerum anterius; and posteriorly, to the point where the tentorium cerebelli is attached to the tip of the posterior clinoid process.

In this, the external wall, it is generally stated, that we find the trunks of the third and fourth pairs of nerves, imbedded in and intimately united with the membrane which forms it. This opinion, however, is not generally correct, for instead of the dura mater being intimately adherent to the periphery of these nerves, we have often found it in the form of a distinct canal, lined with a tubular prolongation of the arachnoid membrane, and extending as far as the limits of the external wall of the sinus. Beyond this, the dura mater forms the external fibrous covering of these nerves. This tubular prolongation of the dura mater and arachnoid membrane, is easily seen extending around the trunk of the third pair of nerves.

This circumstance, viewed pathologically, is of importance, in so far as it points out to us anatomically the first step towards the formation of those large cystic tumors which sometimes appear on the upper part of the face, in hydrocephalic fœtuses, and which tumors

communicate with the cranial cavity through the roof of the nose.

In all these cases, there is also considerable malformation, by deficiency of the ethmoid, sphenoid, and frontal bones.

The fifth pair of nerves lie to the outer side of the walls of the sinus; whilst the sixth pair, with the carotid artery and its plexus, lie within its cavity. These parts, however, need not be mentioned farther, as they do not bear upon our present subject.

The cavernous sinuses result from the expansion of the ophthalmic sinuses, but besides these large trunks, we have a number of other veins pouring their contents directly into the cavities of the sinuses.

Of these, the first are the veins coming from the anterior cranial fossa, and a part of those which are returned from the middle cranial fossa. The remainder of these latter branches usually open into the superior petrosal sinus.

Occasionally, there are also a few branches from the inferior surface of the anterior and middle lobes of the cerebrum; but these latter, as well as the anterior meningeal veins, generally open into and form that additional sinus, about to be described.

Leading from the cavernous sinus on either side, we find three large trunks.

The first is the smallest, and leads downwards from the floor of the cavity, and passing through the foramen lacerum medium, becomes the superior pharyngeal vein.

The second efferent vein is the superior petrosal. This runs outwards between the lamina of the tentorium cerebelli, at its attachment to the posterior superior margin of the petrous portion of the temporal bone, and, ultimately, pours its contents into the lateral sinus; whilst this latter sinus lies in the sigmoid groove of the squamous division of the temporal bone.

The third efferent vein, is the inferior petrosal, which is considerably larger than the preceding. This vein, at first, runs directly downwards, and then a little outwards over the suture, between the apex of the petrous portion of the temporal and the basilar process of the occipital bones, and opens into the lateral sinus, as it is about to emerge from the cranial cavity by the foramen lacerum posterius.

The cavities of the cavernous sinuses are connected together by means of two

transverse branches. One, generally the smallest, passes in front of the infundibulum and pituitary gland, and receives the name of the circular; whilst the second and largest passes behind these two bodies, and is called the elliptical sinus.

By means of these two branches, a very free connection is kept up between the cavities of the two cavernous sinuses; and when the whole are viewed together, a perfect circle can be formed, and this, in honour of its discoverer, receives the name of the circle of Ridley.

Into these transverse branches we find a number of small branches opening.

Some of these come from the substance of the pituitary gland, others from the anterior and inferior part of the walls of the third ventricle, and these open into the circular or anterior transverse branch.

In their course to this vein, they run through the locus perforatus anterior, and receive in this course the small veins from the loose subarachnoid tissue in the anterior concavity of the optic commissure.

Another set of branches come from the posterior part of the walls of the third ventricle, and running through the locus perforatus posterior, receive in their course the veins from the surface of the crura cerebri, and around the roots of the third pair of nerves, and the loose tissue in the posterior concavity of the optic commissure, and they, ultimately, open into the posterior or elliptical sinus.

Having thus described the general anatomical peculiarities of the cavernous sinus, we shall now in the second place describe that additional sinus which we have found in its external wall.

This sinus, so situated, is formed entirely by the splitting of the dura mater, which forms this wall of the cavernous sinus. In length, it generally exceeds the latter sinus; but its depth, as taken from above downwards, is by no means so great. Anteriorly, its cavity commences about a quarter of an inch external to that of the cavernous, and is placed entirely under cover of the small wing of the sphenoid bone. From thence it sweeps forwards and inwards, and at first inclines a little downwards, thereby causing it to assume a lunated form; the concavity of which is placed superiorly, and the convexity being directed downwards and outwards, and lying over the body of the Gasserian ganglion. Posteriorly, it terminates a little in front

of the posterior clinoid process, in a small efferent vein, which proceeding outwards over the trunk of the fifth pair of nerves, opens into the superior petrosal sinus, immediately above the internal opening of the meatus auditorius internus.

The superior margin of the sinus is concave, its inferior is convex; the external wall is comparatively thin, whilst the internal is very thick, and forms the external side of the cavernous sinus.

In the superior part of this septum, we find the trunks of the motor oculi and trochlearis nerves, lying as we have already described, in distinct canals, formed by the splitting of the membrane which constitutes the septum.

At the part of the septum where they are situated, there is a considerable increase in its thickness.

The average length of the cavity of the sinus is about half an inch; but it varies much in this respect. In some instances it extends to a considerable way beneath the small wing of the sphenoid bone, in the immediate situation and direction of the foramen lacerum anterius.

The principal veins, which pour their contents into this sinus, are those which come from the fissure of Sylvius; but the vein which evidently forms it by its direct expansion, is the anterior meningeal vein.

This vein returns all the blood which has been circulated in the membrane lining the anterior cranial fossa, and the different branches which form it run outwards toward the termination of the small wing of the sphenoid bone. There they unite, and form a trunk of considerable size, which is placed between the lamina of the sphenoidal fold of dura mater. From this point, the vein passes at first directly forwards, following the direction of the free margin of the small wing of the sphenoid bone, and after a little it inclines downwards, so that, in its course to the external wall of the cavernous sinus, it crosses the foramen lacerum anterius, generally close beneath the anterior clinoid process; but occasionally it is placed about half an inch external to it. On arriving opposite the anterior extremity of the cavernous sinus, this trunk expands, and forms the cavity of the sinus.

The large middle cerebral, with one or two small branches from the anterior cerebral veins, in the commissura magna

cerebri, at its inferior termination, open into the primary trunk of the sinus, immediately external to the anterior clinoid process. Along the whole of the course of the primary trunk, whilst it lies in the sphenoidal fold of dura mater, there are several branches running into it, which come from the fissure of Sylvius, and the approximated margins of the anterior and middle lobes of the cerebrum. These latter branches are always truncated in the removal of the brain from the cranial cavity, and by tracing them along to their termination, we have a very sure method of exhibiting the cavity of this sinus.

It was by so doing that we were led to observe its existence; for the usual mode recommended for the displaying of the cavity, and the contents of the cavernous sinus, generally destroy its walls so much, as to render the demonstration of the existence of the sinus now described, very difficult and unsatisfactory.

Along with these different veins, which open into the primary trunk of the sinus, we have often noticed a considerable branch coming from the vein which accompanies the middle meningeal artery along the dura mater, lining the roof of the cranial cavity. This branch joins the primary trunk at the apex of the small wing of the sphenoid bone.

Occasionally some of the veins in the fore part of the middle cranial fossa open into it from below, but these branches more frequently open into the cavernous or superior petrosal sinuses. We have never seen any branch from the orbital cavities join either the primary trunk, or the cavity of the sinus, nor have we ever been able to trace a connection between its cavity and that of the cavernous sinus.

The efferent vein of the sinus has already been described. It is about an inch in length, and is small when compared to the size of the cavity of the sinus. It runs backwards and outwards, crossing over, in its course, the trunk of the trifacial nerve, immediately behind the Gasserian ganglion, and opens in an oblique manner into the superior petrosal sinus, immediately above the internal opening of the meatus auditorius internus.

REMARKS

ON

THE PHARMACOPŒIA OF THE
ROYAL COLLEGE OF PHYSICI-
CIANS, EDINBURGH, 1839.

BY RICHARD PHILLIPS, F.R.S. &c.

[For the London Medical Gazette.]

(Continued from p. 761 of vol. ii. for 1838-9.)

AFTER the lapse of a longer interval than I had anticipated, I resume my observations on the Edinburgh Pharmacopœia.

Acetum destillatum.—In my remarks already published, I showed that by the College process a considerable quantity of vinegar was wasted, owing to their directing too small a portion to be distilled; the amount of this loss I have now ascertained. From f $\frac{3}{4}$ 40 of English vinegar I distilled, as ordered, f $\frac{3}{4}$ 30; its density was 1006. I afterwards obtained f $\frac{3}{4}$ 5 more, and its density was 1009.3; the former contains about 3.53 per cent. of acetic acid, and the latter 5.4, consequently the acetic acid contained in the $\frac{3}{4}$ 30 amounted to 466 grains, and that in the $\frac{3}{4}$ 5 to 120 grains; so that owing to the directions for distilling only $\frac{3}{4}$ 30 instead of $\frac{3}{4}$ 35, scarcely four-fifths of the vinegar which might be obtained are actually procured, and for this very considerable loss no adequate reason can be assigned. I also distilled $\frac{3}{4}$ 30 and $\frac{3}{4}$ 5 from $\frac{3}{4}$ 40 of French vinegar; the results corresponded so exactly with those above stated, that it is needless to describe them.

Acidum Aceticum.—The directions for preparing this acid are as follows:—

“Take of acetate of lead any convenient quantity: heat it gradually in a porcelain basin by means of a bath of oil or fusible metal (8 tin, 4 lead, 3 bismuth) to 320°F.; and stir till the fused mass concretes again: pulverize this when cold, and heat the powder again to 320°, with frequent stirring, till the particles cease to accrete. Add six ounces of the powder to nine fluid drachms and a half of pure sulphuric acid contained in a glass matrass: attach a proper tube and refrigerator; and distil from a fusible metal bath with a heat of 320° to complete dryness. Agitate the distilled liquid with a grain or two of red oxide of lead to remove a little sulphurous acid, allow the vessel to rest a few minutes, pour off the clear liquor, and redistil it. The density should not be above 1065.”

I have attempted to follow this pro-

cess, and if (which I very much doubt) any one else ever did, he must, I think, have found that it is much more easy to fail than to succeed in it. The College evidently intend to procure glacial, or the strongest acetic acid; for what medicinal use it can be required, I shall not enquire; I may perhaps make another attempt to prepare it. In the meantime, I will state, as the results of experiments which I have already performed, some of the more glaring imperfections (to use a gentle expression) of the directions issued by the College.

In the first place, that the acetate of lead may be rendered anhydrous, it is to be heated to 320° of Fahrenheit, stirred till the mass concretes, to be pulverized when cold, again heated to 320° till the particles cease to accrete;* no *accretion*, however, occurs after *concretion* and pulverization, so that one-half of these directions is needless.

In the second place, doubting whether so high a temperature as 320°, and the troublesome means of applying it, were requisite to deprive acetate of lead of its water of crystallization, I heated ten oz. of this salt in a porcelain vessel over boiling water, occasionally stirring it. When it had ceased to lose water, there were left 8 ounces and 264 grains, which is within a few grains of what the salt ought to have weighed if perfectly anhydrous, taking the equivalent of it when crystallized at 190, and as containing three equivalents of water.

Thus, then, it is evident that the heat of boiling water, and occasional stirring, are capable of effecting what is directed to be performed with constant stirring at 320°, by a fusible metal bath, the use of which is inconvenient and expensive; or by an oil bath, which has the additional demerits of being disagreeable and dangerous. In both these methods, and especially the former, it is difficult to keep the matrass immersed in the heated fluid; the use of a thermometer is required, and it must be constantly watched lest the temperature should rise too high, which in the fusible metal bath it must have a great tendency rapidly to do.

In the third place, I shall consider whether acetate of lead is the salt best adapted for yielding acetic acid. My first objection is, that it is an extremely inconvenient substance to mix with the sulphuric acid required to decompose

* I have not been able to find this word in any dictionary which I have consulted.

it, for they form a most tenacious compound. As a preliminary trial, on a very small scale, of the mode in which these substances would act upon each other, I added 30 minims of the acid to 140 grains of the acetate, and mixed them with a glass stirrer, which was suffered to remain in the mixture, and was retained by it with such force, that it required a weight equal to several ounces to separate them; this renders it difficult to mix the ingredients by agitation, and to do so by stirring in the matrass is impossible. Such indeed is the tenacity of this mixture, that cases may arise in which it may be usefully employed as a cement.

In the fourth place, the use of acetate of lead is highly objectionable on account of the extreme insolubility of the residual sulphate of lead, and the consequent difficulty in clearing the matrass for a second operation. Another objection is its cost compared with that of other acetates; acetate of soda, for example, is a salt which may be advantageously used for preparing glacial acetic acid; its original cost is, indeed, the same as that of acetate of lead, but then 100 parts of this contain only 26·8 of acetic acid, whereas 100 of the soda salt contain 37·23. I find that it also may be rendered anhydrous at 212°. In an economical point of view, therefore, the use of acetate of soda is more advantageous than that of acetate of lead, in the proportion nearly of 14 to 10, and there is the great contingent benefit of the easy removal of the residual sulphate of soda from the matrass, and this is a salt of some little value, whereas the sulphate of lead obtained by the College process is of no use whatever.

Acetate of lead was probably selected by the College in consequence of the statement of Despretz (*Ann. de Chim. et de Phys.* t. 43, p. 223) that he had procured crystallizable acetic acid from it; this information is accompanied with the assertion that the process for preparing the acid of this strength is kept a secret. That it may have been so in France is probable, but it was published in England 20 years since by Messrs. J. and P. Taylor, in the sixth volume of the *Royal Institution Journal*; they obtained the glacial acid by using fused acetate of soda, oil of vitriol, and glass retorts, and most probably a common sand heat, for they make no mention of metal or oil baths as requisite to the success of the operation. I may here

mention a curious distinction made by the College, on the subject of modes of heating: when the acetate of lead is to be deprived of its water of crystallization by exposure to a heat of 320°, we may perform the operation "by means of a bath of oil or fusible metal," but when the acetate of lead is to be decomposed at the same temperature, we are directed to "distil from a fusible metal bath;" so that in the first part of the operation we are at liberty to use the better of two bad methods, while in the second, we are restricted to the employment of the worse.

The necessity for having recourse to sulphuric acid purer than that of commerce I cannot discover; if it be merely on account of its greater strength, the acid might be obtained of equal density by simple concentration, which is an operation of much less risk than that of rectification. Messrs. Taylor appear to have used common commercial acid.

Any sulphurous acid which the acetic acid may contain, the College have directed to be removed by agitating it with a grain or two of red oxide of lead, and then redistilling it. Messrs. Taylor used acetate of lead for this purpose, and so, in point of fact, do the College; for when the red oxide is put into acetic acid, it is immediately separated into protoxide and binoxide, and the acetate which the former yields is instantly decomposed by sulphurous acid, whereas the action of sulphurous acid upon dentoxide of lead, so as to become sulphuric acid, is comparatively slow.

As the College have thus limited the quantity of red oxide of lead to be used, let us inquire what must have been the greatest amount of impurity which they supposed the acetic acid to contain; for I know not what other consideration could have induced the limitation of its employment to two grains, when a considerably larger quantity of the acetate of lead than absolutely required would have occasioned but little loss, and no inconvenience.

Two grains of red oxide of lead are equivalent to 1·3 gr. of protoxide, and 0·7 gr. of binoxide; the protoxide is capable of combining with 0·37 gr. of sulphurous acid, and the excess of oxygen in the binoxide is sufficient to convert 0·18 grain of sulphurous into sulphuric acid; the quantity of sulphurous acid, therefore, which the College suppose the product to contain, cannot exceed 0·55 of a grain.

Now it will appear by a calculation, which it is not necessary to state, that the ingredients used by the College ought to produce more than 1000 grains of glacial acetic acid, and it is a provoking circumstance, if it be well founded, that this product should require the wasteful operation of being redistilled on account of its containing only about 1-2000th of its weight of impurity; or, indeed, if the smaller quantity of deutoxide of lead mentioned by the College be sufficient to purify the acetic acid, the sulphurous acid cannot exceed about 1-4000th of the weight of the acid obtained.

Until more leisure than I have lately had will permit me again to attempt the preparation of this acid according to the directions of the College, I shall quit the subject with remarking, that whether the product be more or less pure than the College suspect, or whether it has a "density not above 1068·5," as stated at p. 2 of the Pharmacopœia, or "not above 1065," as directed at p. 44, the process is to be strongly condemned for its inconvenience and expense.

Acidum Nitricum purum.—The formula of the London College is adopted, and is a great improvement on the former process.

Acidum Nitricum dilutum.—The directions for preparing this are as follows:—

"Mix together three fluidounces of nitric acid (commercial), and four fluid ounces of water. If pure nitric acid be used, four fluidounces of it must be mixed with six fluid ounces of water. The density of this preparation is 1290."

As the College state the sp. gr. of the dilute acid is 1290, I conclude that they intended, and very properly so, that its strength should be similar to that of their former Pharmacopœia, or that it should contain about 40 per cent. of real nitric acid; for it appears by Dr. Ure's table that dilute nitric acid, of density 1291, contains 39·45 per cent.; whether this accuracy, on the part of the College, was the result of calculation, or of experiment, it is unnecessary to inquire; unfortunately, however, it attaches to one only of the two modes of preparation directed, or that in which the pure acid is used; I found the sp. gr. to be 1292.

The directions for using commercial nitric acid and water were probably the result of calculation, and that a wrong

one; for experiment tells a very different tale from that of—"the density of this preparation is 1290."

It is stated by the College that commercial nitric acid has a density of "at least 1380;" that which I employed was of 1381 density. According to Dr. Ure, acid of 1380 contains, as nearly as possible, 53 per cent. of real acid; and let us try, by calculation, what ought to be the density of a mixture of three fluidounces of nitric acid of 1380, and four fluidounces of water. A fluidounce of a liquid, of density 1380, weighs 603·75 grains; three fluidounces, therefore, weigh 1811·25 grs., and, as it contains 53 per cent. of real acid, the three fluidounces contain 960 grains, within a small fraction, and the four fluidounces of water weigh 1750 grains. The weight of the mixture is, therefore, 3561·25 grains; and, as it contains 960 of real acid, it amounts to 26·9 per cent.

Not trusting, however, to calculation, I prepared the diluted acid by mixing three fluidounces of nitric acid, of density 1381, with four fluidounces of water, and I found the sp. gr. of the mixture was 1189·7 instead of 1290, as stated by the College, and, according to Dr. Ure, it contains, as nearly as possible, 26·3 per cent. of real acid, differing only 0·6 per cent. from the above calculation.

Having thus proved my assertion that if the proportions of acid and water above used were the result of calculation, that it must have been an erroneous one, I proceeded to compare the strength of the two dilute acids by experiment.

First, I added a small quantity of water to a fluidounce of that variety of the College dilute nitric acid which is prepared with nitric acid of density 1·5; its sp. gr. as already mentioned, I found to be 1292 instead of 1290, as stated by the College; the difference is quite immaterial. Into this mixture I put a piece of marble, and found, when the action was over, that 209 grains of it had been dissolved. An ounce of the dilute acid weighed 565·25 grains, and, as this dissolved 209 grs., 100, of course, dissolved 36·97 grs., and as 50 of carbonate of lime = 54 of nitric acid, 36·97 = 39·72, the per centage of real nitric acid contained in the nitric acid thus prepared, agreeing almost precisely with the results of calculation.

Secondly, I added a little water to a fluidounce of the College dilute acid,

which had been prepared with acid of sp. gr. 1381; its density, as already stated, was 1189.7, and the weight of a fluid ounce 520.5 grains; it dissolved 127.3 grains of marble. Then $520.5 : 127.3 :: 100 : 24.45$, and as 50 of the carbonate = 54 nitric acid, $24.45 = 26.40$, exceeding by only 0.1 grain the strength as indicated by calculation. It is, therefore, evident, both from calculation and experiment, that the strengths of these varieties of dilute nitric are, by weight, to each other as 100 to 66, and by volume as 100 to 60.

Thus it appears there is a difference of 40 per cent. in the dilute nitric acids prepared according to the two modes directed. In addition to this, I may remark that, at p. 104, in the formula for *Hydrargyri oxidum rubrum*, the dilute nitric acid is directed to be of sp. gr. 1280; this, however, is most probably a mere misprint.

I shall now exhibit an example of the knowledge which the College possess of the power of the dilute nitric acid, by examining their mode of using it in the preparation of

Nitrate of lead.—The formula is as follows:—

“Take of lead, six ounces; diluted nitric acid, six fluidounces; water, six fluidounces. Mix the acid and water, and dissolve the lead with the aid of a gentle heat; concentrate the solution, and set it aside to cool and crystallize.”

Six ounces contain 2880 grains, and this quantity of lead combines with 221 of oxygen to form 3101 grains of protoxide. When a metal is oxidized by nitric acid, and converted into protoxide, an equivalent of the acid, 54, is decomposed into three equivalents of oxygen, 24, which combine with the metal, and one equivalent of nitric oxide, which is evolved in the gaseous state. As then 24 of oxygen require 54 of nitric acid for their production, 221 of oxygen, the quantity required to convert 2880 of lead into protoxide will require 497 grains.

One equivalent (or 112 of oxide of lead) takes for its conversion into nitrate 54 of nitric acid, therefore 3101 grains will require 1495 of the acid for the same purpose, making the whole quantity requisite for oxidizing and combining with the lead 1992 of real nitric acid. I have just shewn that the College have given such directions for the preparation

of dilute nitric acid as to yield it of the density either of 1292 or 1189.7. Supposing, therefore, the operator, in making nitrate of lead, may have chanced to prepare his dilute nitric acid with commercial nitric acid, and, consequently, to have obtained the dilute acid of sp. gr. 1189.7, let us examine how this would have answered his purpose in the quantity directed. I have stated that a fluidounce dissolves 127.3 grains of carbonate of lime = 137.5 of real acid; six fluidounces, therefore, contain 825, of which 497 being required for the oxidization of the lead, there will remain 328 to convert it into nitrate instead of 1495 necessary to produce the effect.

It might indeed be supposed, that it is intended by the College merely that the acid should be saturated with the lead, and that the excess of metal should be rejected; this interpretation cannot, however, for a moment be admitted, for the directions are to “dissolve” the lead in the acid, not to *saturate* the acid with the lead.

Indeed, it will be seen, which I could hardly have suspected would have turned out to be the case before making the calculation, that even supposing the whole quantity of the lead to be presented to the acid already in the state of oxide, it could not be formed into nitrate, for we should have 3101 of oxide, and only 825 of acid, instead of 1495 as required.

The operator being thus disappointed in using the more economical diluted nitric acid, I will suppose that he afterwards employed the more expensive and stronger preparation, obtained by mixing, according to the directions quoted, four fluidounces of nitric acid of density 1500, with six fluidounces of water: with this diluted acid he might reasonably expect to fulfil the mandate of the College; for no one without examination would be justified in arriving at the monstrous conclusion, that though the College had directed diluted nitric acid to be so obtained, as to yield preparations of two very different degrees of strength, neither of them was sufficiently strong to answer the purpose. But let us see how this matter stands: it has been mentioned that the stronger dilute nitric acid of the College has a density of 1292, which agrees very nearly with their statement of 1290, and I will give them the benefit of the difference. Six

ounces of lead, it has been already proved, require 497 of real acid for oxidization and 1495 for combination after it, = 1992 of real nitric acid. A fluid-ounce of nitric acid of 1292, dissolves, as already mentioned, 209 of carbonate of lime, equivalent to 225.7 of real acid, which, multiplied by 6, gives 1354 as the whole quantity of acid contained in the diluted acid employed; so that in this more favourable case it appears that the acid is deficient by no less than 638 out of 1992, or nearly one-third.

After these statements it may be thought quite superfluous to add another word in demonstration of the true nature of the formula for preparing nitrate of lead; but I have not yet done with it. It is well known that lead is oxidized more cheaply and conveniently by the action of heat and air, than that of nitric acid; and knowing this, I am utterly at a loss to conjecture what freak of fancy induced the College to direct the use of the metal instead of litharge. It is employed by them in preparing the acetate and diacetate of lead; and if properly directed in these cases, no objection could possibly arise to it in that of the nitrate.

The expense of the nitric acid is increased by one-third, the operation is much more tedious, and is attended with the formation of a highly disagreeable vapour, which does not occur when litharge is used.

It is ordered that six fluidounces of water should be added to the six fluidounces of dilute nitric acid; and when the lead is dissolved, we are directed to "concentrate the solution, and set it aside to cool and crystallize."

Now as the College direct the whole of the six ounces of lead to be converted into nitrate, we must suppose that there would be formed, in their opinion, 4596 grains of nitrate of lead; and, as according to Berzelius, this salt requires 7.5 times its weight of cold water for solution, 4596 would require 34,470 gr.

Let us, then, examine into the necessity for the concentration of the solution directed by the College. The six fluid ounces of dilute nitric acid, of sp. gr. 1292, weigh 3391 grains, of which 1354 are acid and 2037 water; and this added to the 2625, the weight of the six fluid ounces, give 4662 grains as the whole quantity of water present at the commencement of the operation; so that without making any allowance whatever for the loss of water during the

digestion, we are directed to concentrate a solution already containing more than seven times as much salt as the water is capable of dissolving when cold.

Not trusting, however, to calculation, I put six ounces of lead into the quantities of the stronger dilute nitric acid and water, directed by the College, and heated them in a porcelain vessel for about two hours; of the 2880 grains of lead, 910 remained unacted upon, and consequently 1970 were dissolved. On referring back to what I have stated respecting the solvent power of the dilute nitric acid employed, it will be seen that calculation is confirmed by experiment, quite as nearly as could be reasonably anticipated. I have stated that 1992 of real acid are theoretically required to convert 2880 of lead into nitrate, and I have shown that six fluid ounces of nitric acid, of density 1292, contain only 1354 of real acid. As then, 1992:2880::1354:1957, the quantity of lead which by theory ought to be dissolved; whereas, as above stated, it was 1970 by experiment.

I did not "concentrate" the solution as ordered, but set it aside to crystallize without it, and I readily obtained 1620 grains of the crystallized nitrate, which it will be seen by the quantity of lead dissolved is rather more than one-half of the whole quantity formed, for 104:166::1970:3144, the nitrate actually produced.

In concluding my remarks on this preparation, I think that I am justified in repeating my opinion, that if these directions for preparing nitrate of lead were given theoretically, the calculation was erroneously made; and this is the most favourable supposition that can be offered in excuse for the egregious mistakes which I have exposed; for it is not credible that the College would have ordered lead to be dissolved by a menstruum which experiment had shown them was insufficient to effect it, or that they would have directed evaporation to produce crystallization, if they had found by experiment it would occur without it.

I had prepared the foregoing remarks, and expressed my intention of continuing them, when I was accidentally informed that the President of the Royal College of Physicians of Edinburgh is engaged in editing a Dispensatory. Under these circumstances, I shall at present discontinue my observations,

trusting that some difficulties which have occurred to me, but which I have not yet had time to put to the test of experiment, may receive such explanations in the work alluded to, as may render unnecessary any further interference on my part.

VENEREAL AFFECTIONS OF NOSE.

To the Editor of the Medical Gazette.

SIR,

I HAVE derived much benefit in six cases of obstinate ulceration of the nose, and neighbouring parts, from the daily application of two, three, or four leeches to the gum on the upper jaw. All of these cases had assumed the inveteracy, obstinacy, and other characters, of that destructive process to which the name of lupus has been given. I had derived so much benefit in cases of venereal inflammation and its consequences from this practice, that I was induced to try it in the cases mentioned; and though they had resisted every method I had ever heard of for months, they yielded to the practice mentioned. The first applications brought relief from pain, reduced the redness and livor of surrounding parts, a gradual amelioration ensued, and, in the worst case, the cure was accomplished in forty-eight days, 140 leeches having been applied.

I can, therefore, with great confidence, recommend the above practice in cases of venereal affections either of the soft parts or of the bones of the nose, and, as far as six successful cases authorize me, I would advise the same in cases of lupus.

Of course, none of the measures calculated to improve the general health, or local applications likely to do good, are interfered with, and these should be diligently administered. I have been informed of one case of failure of the remedy proposed; but, before I can attach weight to it, I should wish to be quite sure that it was steadily pursued without a single day's interruption. Sincerely do I hope others may derive that benefit from the measure which has fallen to my lot.

I am, sir,

Your obedient servant,

ALEX. J. HANNAY, M.D.

Surgeon to the Lock Hospital and the Royal Infirmary.

22d April, 1840.

FARCY AND GLANDERS.

To the Editor of the Medical Gazette.

SIR,

THE enclosed remarks, prompted by the perusal of Mr. Brush's cases, are, should you think them worth notice, quite at your service.

Your obedient servant,

WILL. PERCIVALL, M.R.C.S.

Vet. Surgeon, First Life Guards.

Hyde Park Barracks,
May 4, 1840.

So long, so great a debtor, as veterinary science is to human medicine, it would be the height of ingratitude—to say nothing about the philanthropy of the case—in her to withhold any aid, be that ever so slight, she deemed might prove serviceable to her scientific sister. The subjects, farcy and glanders, have occupied the most serious attention of veterinarians from even the commencement of their art. In a former age, Lappose, the celebrated French veterinarian, pursued his inquiry into the nature of these diseases with an ardour which, as he went on, ripened into the warmest zeal, from the circumstance of his having imagined he had discovered a remedy for this opprobrium of his art. His views, however, turned out fallacious; being grounded upon the supposition that he had to combat with but a *local* affection, while in reality it was a *constitutional* one. Sainbel, the first professor appointed at our own Veterinary College, also turned his attention to these subjects; but his career proved too short to enable him to advance them any great deal. In his successor's (Professor Coleman) time, the important facts became developed, that farcy and glanders were the same disease, affecting different parts or tissues; that inoculation with the matter of farcy would produce glanders, and *vice versa*; that farcy had for its seat the skin, glanders the schneiderian membrane; that both consisted in inflammation and suppuration of the superficial order of lymphatics; and that the chain of little abscesses, followed by exulcerations, was owing to the circumstance of the valves of the absorbent vessels (apparently from their comparatively low degree of organization) not taking on the ulcerative action. That both farcy and glanders are contagious diseases admits no longer of doubt; but that

either is communicable, except through direct contact, or inoculation of some sort, we have no facts to prove. Some years ago, these diseases among horses were extremely prevalent; our regiments of cavalry evinced this, as well as other horse establishments, and, indeed, the country at large. But, now-a-days, such is not the case. A better plan of ventilation and training has done much to prevent, and improvement in veterinary medicine has done much to cure, the disease; for be it known, although we do not arrogate the possession of any specific, there are forms and stages in which the disease, in many cases, is curable.

In reference to the cases published by Mr. Brush, there cannot be a question about the ill-fated nurse being contaminated by the knacker; the abrasions upon her hand imbibed the poison; the arm of that hand, and the same side of her body, became the seat of disease. Had not contact, nay, even inoculation taken place, I should say, the poor nurse would have escaped. Veterinary surgeons have no notion of *inhaling* infection from glandered or farcied horses; their only fear is, that some sore or cut upon their hands may meet with the discharge from their patient's nose, or some one of his farcy ulcers. It should therefore be, I take the liberty to recommend it in our hospitals, an affair of extreme caution in those cases, that those in attendance should not subject themselves to the possibility of becoming inoculated. I believe they may breathe the same atmosphere with impunity.

At the commencement of either farcy or glanders, but of the former in particular, we veterinarians find depletive remedies most useful. When a limb is much inflamed and tumefied, and chorde in the course of the absorbents, and sensitively tender to pressure, we are desirous to draw blood and to purge briskly; and in addition, we are often compelled to do what seems irreconcilable with this inflammatory condition of limb, which is, to force the animal to make use of it, by walking exercise. Were it not for the exercise, which is repeated once, sometimes twice a day, experience has taught us, that the tumefaction, and with it, irritation and fever, would augment to a degree even to threaten the animal's life. After we have subdued the inflammatory action and swelling, so that the farcied parts appear to have

become permanently infiltrated and comparatively without feeling or callons, we find most benefit from a combination of tonic with diuretic medicine. The mineral tonics, the sulphates of copper and iron, have proved very serviceable. And last of all, change of air and living, turning out to grass in the summer season, has often completed the cure.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

POOR LAW COMMISSIONERS—

THEIR REPORT TO LORD NORMANBY.

A MISERABLE complaint of the Poor Law Commissioners is now lying before us*. They moan over their extreme unpopularity, and the possible discontinuance of their salaries, and beg most earnestly that their unpopularity may cease, and their wages go on. But we fancy that, as the ancients express it, the gods will grant only one-half of the Commissioners' prayers; they may still continue to draw their comfortable pay, but the dislike to their proceedings will increase in the same proportion that they are understood. The Commissioners, in this their melancholy defence, bear ample testimony to their very remarkable unpopularity. Many of the conductors of the newspaper press, they inform us, are against them; poor-law horrors have been introduced into works of fiction; and inflammatory speeches against the new law have been made at public meetings. The pamphlet entitled "*Marcus on Populousness*," recommending the painless extinction of

* Report of the Poor Law Commissioners to the most noble the Marquis of Normanby, her Majesty's principal Secretary of State for the Home Department, on the continuance of the Poor Law Commission, and on some further amendments of the laws relating to the relief of the poor. With appendices. London, 1840.

children, was attributed to the Commissioners; and they have reason to think that the calumny was “believed by many of the simple and credulous persons to whom it was addressed.” Curiously enough, “the poor-law amendment act, though essentially of a popular tendency, bears outwardly an unpopular appearance*,” and this is the case to so singular a degree, that, if you take the deeds of an Ogre in a child’s story-book, and attribute them to the Commissioners, the tale finds instant credence. Never were philanthropists so misrepresented. Few would have ventured to say of Howard that he intended to throw all the prisoners in England into vaults, like the dungeons reserved in the happy days of Queen Bess for the professors of an unparliamentary creed. To accuse Sir Samuel Romilly of wishing to revive the code of Draco, or Wilberforce of supping on baked negro, would have seemed extravagant; and had it been asserted that the man of Ross designed to set the Wye on fire, the accusation would have been more dangerous to the accusers than to Mr. Kyrle. Not so with the amiable functionaries of Somerset House: nothing is too bad to be believed of them. Just hear their own account in the present volume, reprinted from their second annual report. It is Mr. Gilbert who speaks, in his report on Devon, dated June, 1836.

“Amongst other ridiculous statements circulated, the peasantry fully believed that all the bread was poisoned, and the only cause for giving it instead of money was the facility it afforded for destroying the paupers; that all the children beyond three in a family were to be killed; that all young children and women under eighteen were to be spayed; that if they touched the bread they would instantly drop down dead; and I saw one poor person at North Molton look at a loaf with a strong expression of hunger, and when it was

offered to her, put her hands behind her, and shrink back in fear lest it should touch her. She acknowledged that she had heard of a man who had dropped down dead the moment he touched the bread. It was also believed, that to touch the bread was like ‘taking bounty,’ and the guardians would immediately seize them, kill their children, and imprison their parents.”

This was pretty strong, and certainly confirms what the Commissioners say of the act bearing “outwardly an unpopular appearance.” When the poor people of Devonshire, however, found that the loaves were harmless, and that it was merely workhouse diarrhœa, and not arsenical poisoning, which they had to dread, they rejoiced greatly. “As soon as the intentions of the law were understood, the most riotous submitted, and received the alterations gladly.”

Yet though the apprehensions of poisoning and spaying may have subsided, the belief that the Commissioners are haunted by an insane dread of “surplus population” still prevails; and the disbelief of their intention to relieve the poor is universal. The workhouse is the last asylum of the old and the sickly; and, when the opponents of the act see the pains taken to render this sad refuge utterly intolerable to its friendless inmates, they naturally turn a deaf ear to the self-praises of the Commissioners. But even the supporters of the act would smile sardonically if you asked them whether it was intended to make the indigent more comfortable; and, in their franker moments, would avow, that its chief object was to diminish the rates: while your staunch Malthusian, untaught by the experience of ages, would look forward to the gradual denial of all relief, as a sharp but sure method of “teaching the poor to rely on their own resources,” and forcing them to lay up a provision for age and sickness out of seven shillings a-week.

Hence the unpopularity of the new law bids fair to be permanent; for the

* Report, p. 28.

repugnance of the humane will not be neutralised in its social effect by the cold approbation of the less generous rate-payers. Indeed, in many instances, the householder, though he exults in saving £1. 9s. a-year, will not have much to say in favour of those who have put the money in his pocket. It is a common thing to love the treason, but hate the traitor; and he will think the Commissioners a very shabby set of fellows.

But let us now consider, in detail, a few of the pleas of these prisoners at the bar of public opinion.

They assert that, before the passing of the new act, the amount of the poor-rates had become grievously oppressive in most parts of the country, "and in some places had become nearly intolerable, so as to threaten the abandonment of the land by the proprietors."

If ever there was a *bam*, to speak in Swift's dialect, this was one; but, to do the Commissioners justice, it is not one of their invention. When it is known that a committee is sitting to collect evidence for a particular purpose, evidence is never wanting; and some part of it commonly consists of mere moonshine. The intention of certain proprietors to cut and run, in order to escape the poor-rates, was rich indeed; and, though we recollect it was set forth with great gravity six years ago, we hardly expected to see it revived in a new report.

The next point on which the Commissioners congratulate themselves, is the abolition of the payment of wages out of the rates.

Under the old system, as our readers are aware, a farmer paid a man, suppose seven shillings a-week; and, if the labourer had a large family, perhaps five more were added by the parish, so as to make up a decent subsistence. Still, there were objections to the method; and it was plausibly argued by the economists, that the labourer was degraded

into a pauper, and that his wages would be as high, or higher, if parish aid were withdrawn, and the farmer were obliged to supply the entire subsistence of his labourer. But, alas! it seems fated that Malthusianism is never to prove right in a single instance. The parish aid has been withdrawn, and wages have not risen. In fact, these social problems are so complicated, that no one can tell how they will work till the experiment is tried. The economist reasons ingeniously on his premises; but when his conclusions are falsified by experience, it is found that his premises were insufficient. He has left out one of the moving springs of social life, and his calculation is fit only for the Academy of Laputa. In this particular instance, perhaps, the solution of the difficulty is, that the husbandman is always in so depressed a state, that the farmer can beat down his wages to the lowest point compatible with existence; and he must be defended either by a liberal workhouse, or by an addition to his wages from the common stock. This forms in reality a part of his regular remuneration; and is not considered as degrading. The strongest objection to it is, that those who do not employ labourers pay the farmer's wages for him.

Without a tolerable workhouse, however, as a refuge, the unfortunate husbandman, with his allowance withdrawn, seems in danger of being reduced to barley bread and bare feet, in spite of the generous lessons of the economists, who would teach him, in the cant of the day, to rely on his own resources.

The Commissioners have the face to assert, that "the consequences of this perversion of the natural relations of employer and workman were developed in the agrarian disturbances and fires of 1830 and 1831, &c.;" and they add, that "the causes of evil which we have described have been extinguished." So that the labourer, when he obtained seven shillings wages, plus five shillings

allowance, was irresistibly impelled to rise against his masters; but now that he gets seven shillings, and no allowance, he would not stir—not he—though the Genius of insurrection stood before him, with a pike in one hand, and a torch in the other!

It is allowed by some of the advocates of the new law, that the refusal to give out-door relief to the able-bodied could not possibly be continued during a time of general distress; so that the act would fail precisely at the moment its services were most imperiously required: like Professor Nogo's fire-escape, which, we are assured by Mr. Dickens, was brought wherever it was wanted—the day after the fire!

But even during the present period of comparative prosperity, there are so many of these able-bodied men out of employment, who naturally shrink from incarceration in the workhouse, besides many who belong to the class, just mentioned, of labourers with inadequate wages, that some additional means of support are requisite. Hence, as we learn from the report before us, attempts are constantly made to evade the law, by voluntary rates, highway rates, and by the orders for food given by the union surgeons. In truth, some safety-valves of this kind must be found, or the frame of English society could not stand the pressure. If they were wanting, either the able-bodied must be slowly ground down in workhouses formed expressly, not for the relief of misery, but as a "test of destitution;" or if English manhood refused to submit to this mockery of charity, starvation would appear in a more acute form, and England would be cursed with such scenes as Dr. Alison witnesses in Edinburgh. For instance, he found a young woman "in the last stage of consumption, lying on the floor of a dark room, with a scanty covering of rags, her head resting on a stone. She assured me that she had had no

other resting place for six weeks, and hardly any sustenance, but what had been given her by the poor widow with whom she lived, and who has 9d. a week from the Charity Workhouse. She died there, before I could procure her admission to the Infirmary."*

After this, we cannot sympathize with the Commissioners in their spleen at voluntary rates.

MANAGEMENT OF THE POOR IN SCOTLAND.

To the Editor of the Medical Gazette.

SIR,

I was much gratified (I hope from a better motive than personal vanity) by the notice taken in your journal of my pamphlet, "On the Management of the Poor in Scotland."

The subject has attracted a good deal of attention here; and a pamphlet has been published in opposition to mine, and in defence of the Scottish system, "by David Monypenny, Esq., formerly one of the Senators of the College of Justice," to some of the statements in which I am desirous of drawing the attention of your readers.

The question as to the comparative merits of different modes of providing for the poor, is one which ought to be decided chiefly by comparative observation; and there is, perhaps, no class of men whose observation on the subject can be of so much value as medical men, because there is no other class, equally well-informed and intelligent, who have so many opportunities of observing the *condition and habits* of the lowest class of society in different countries, or parts of this country. Many of your readers must have seen much of the lowest order of people in Edinburgh, particularly when attending dispensaries, and, since then, must have had similar opportunities of observation in English towns, and perhaps in other countries, particularly in Germany; and to them I would beg to address myself.

It is stated in the pamphlet of Mr. Monypenny, (p. 21.) that the opinion of

* On the Management of the Poor in Scotland. 2nd edit., p. 82, note.

the superiority of the Scotch system of management of the poor over that now adopted in England, which I have characterised as a prejudice and delusion of my countrymen, is now "the firm conviction of Englishmen; and, therefore, that the English law is gradually to be administered in the same spirit as ours."

Again, it is stated, (p. 43.) that the "desertion of relatives by relatives," has been introduced into Scotland only by compulsory assessments for the poor; and "only let this measure be extended to all the parishes in the country, and the rates be augmented, and the duty of relatives to the poor with whom they are connected is extinguished for ever."

Now, the questions which I should wish to put to such of your readers as have had opportunities of making such comparative observations as I have mentioned, are these,—

1st, Is it their "firm conviction," that the Scotch system of management of the poor is better than that now in force in England, and that the English system ought gradually to be assimilated to the Scotch; *i. e.* that the workhouses ought to be entirely done away in most parts of the country—all right to relief denied to the able-bodied poor—and the allowances to the aged and infirm, widows and orphans, be reduced to about one-third their present amount?

2dly, Is it consonant to their observation, that among the English poor, in whose favour a compulsory assessment upon the higher orders has been in force for 250 years, the duty of relatives to those with whom they are connected has been thereby extinguished for ever; or even so far weakened, in comparison with that existing in Scotland, as to make it right, for the sake of avoiding such injury to their moral character, to maintain the Scotch system of relief to the poor, under which so many of them habitually undergo the sufferings, and are exposed to the dangers, from fevers and other causes, which I have endeavoured to describe?

I shall feel much obliged by any answers to these queries, addressed either to myself, or to my friend, Dr. Handyside, (10, Shandwick Place,) who is a fellow-labourer with me in this field.—I have the honour to be, sir,

Your very obedient servant,

W. P. ALISON.

Edinburgh, May 2, 1840.

EXAMINERS, LONDON UNIVERSITY.

THOSE Examiners of last year, who were members of the Senate, were re-elected a few weeks since.

Four Examinerships, filled last year by non-senatorial members (*viz.* Messrs. Tweedie, Daniel, Pereira, and Todd) were filled up on Wednesday last (the 6th). Messrs. Daniel and Pereira were re-elected; and Drs. Watson and Sharpey were elected in the room of Drs. Tweedie and Todd.

ACTION FOR LIBEL.

SYME *v.* LIZARS.

MR. SYME, who, our readers are probably aware, is Professor of Clinical Surgery in the University of Edinburgh, recently brought an action for libel against Mr. Lizars, Professor of Surgery in the College of Surgeons. The following is the article complained of, and is contained in Lizars' *System of Surgery*, Part II.:—

"In every operation about the anus, however unimportant it may seem, the operator cannot be too careful in averting hæmorrhage, as many have died from such neglect. This was the fate, indeed, of a respectable apothecary in this city. Nor is it improper, as an additional warning, here to mention another case, which was under the care of our Professor of Clinical Surgery a few years ago. He operated on a gentleman, for a slight fistula in ano; left the part inadequately defended, and dreadful hæmorrhage ensued. The Professor was sent for, arrived, groped about in the anus with his knife, *searching for a needle in a hay rick*—I mean, for a blood-vessel to be tied. Meantime, the life of the patient was saved by *deliquium animi*; but to this day the wound remains unhealed, and the unfortunate man a miserable, nervous invalid, from the excessive loss of blood."

The damages were laid at £1000.

The defence consisted in denying that the passage was false, calumnious, or injurious; or that it was written with the intent of imputing want of skill to Mr. Syme, or with a wish to hurt his good name and reputation. It was then admitted, on the part of the defendant, that he had been misinformed as to Mr. Syme being the party who "groped about" for the vessel; because, though sent for, he was not to be found.

The Lord Justice Clerk summed up, giving an opinion in favour of the prosecutor; to whom the Jury, after retiring for a few minutes, awarded £50 damages.

ROYAL MEDICO-CHIRURGICAL SOCIETY.

April 23th, 1840.

SIR B. C. BRODIE, Bart. in the Chair.

On Severe Injuries of Joints and their Treatment. By RUTHERFORD ALCOCK, Esq. K.C.T.

THE author commenced by shewing that the only information we possessed on so important and complicated a class of injuries was to be found scattered in various medical journals, and chiefly in the works of military surgeons; and that even when all these fragmental data were collected, they were far from furnishing any thing like a complete or comprehensive classification of the various kinds of injuries defined in reference to certain fixed principles of treatment. To supply this was the object in view.

In reference to this class of injuries there not only was the grave consideration of amputation, and the necessity of determining in which cases there was a fair prospect of saving a useful limb, but there were other operative means, such as the excision of the articulating end of a diseased or injured bone, by which a limb might be saved even without all the hazard of the reparative action when the end of the bone was seriously implicated. Cases in which this alternative offered required to be carefully defined.

Many of the general conclusions were founded upon a close analysis of the nature, progress, and results of 96 cases of severe injury to the articulation. Such of those conclusions as were numerical he had thrown into a tabular form, to which he adverted under the following heads:—

Mortality of these injuries in comparison with other kinds, and relative mortality in each articulation.

Comparative frequency of these injuries with those of other parts of the body, and of one articulation.

Causes of mortality in those who died while under treatment for the original injury—those who died after primary or secondary amputation.

From a review of numerical results under these heads, the author passed on to the consideration of particular cases forming types of classes, and the principles of treatment applicable to each. Many highly interesting cases were shortly narrated, proving essential differences between injuries apparently similar in many circumstances, but yet requiring the application of different principles of treatment.

Upon the data of the conclusions drawn from them, the author founded his group-

ing of the injuries into three classes, having reference to certain leading features of treatment.

1st Class, consisting of lacerated wounds external to the capsule. Incised or lacerated wounds penetrating the capsule. Penetrating wounds with abrasion of articulatory surfaces. Simple fractures into joints, with more or less displacement and ligamentous adhesions. Fissuring of articulating surfaces from compound fractures, complete or partial, in the vicinity, but without displacement of bone within the capsule.

In this class are included, those where the great majority of limbs may be saved, and when it should be a principle of practice to attempt it.

2nd Class—Foreign bodies lodged in ends of bones, either not presenting in the articular surface, or on the same level, and smooth. Foreign bodies traversing the ends of bones without detaching fragments. Internal laceration of ligamentous structure, lesion of blood-vessel, with or without temporary displacement of articulatory surfaces.

The second forms an intermediate range between those in which the principle is laid down, that they may be saved, and those in which the contrary rule holds; viz. That the attempt ought not to be made.

These, of all the injuries to joints, most require accurate diagnosis and sound judgment in determining the line of practice, whether to attempt to save, or at once to condemn. The author had succeeded in saving many of these, but it certainly was not always judicious to make the attempt.

In the kind, "Foreign bodies traversing the ends of bones without detaching fragments," an example was presented after the meeting, and examined by many fellows of the society. The author had succeeded in saving a limb, so strong that the man had walked from London to Liverpool. A musket-ball had entered at the inner edge of the patella, fracturing it, and, traversing the internal condyle, came out near the centre of the popliteal space.

3d Class.—Compound fractures into joints, with displacement, and roughened edges. Foreign bodies projecting with articulations, or traversing into extensive injury to structure.

The third class includes those kinds where the principle of practice is to amputate without delay. The injury being of an irremediable character, the system, from the first moment, takes the alarm, and each succeeding hour rapidly diminishes the powers of the patient. He had known only one case (except the hand or foot) recover, where there was fracture into the joint, causing displacement of the roughened edges, and that was of the elbow.

Many valuable preparations were shewn to the society, exemplifying different kinds of injuries to the articulations, and their effects.

PATHOLOGICAL DEPARTMENT.

May 5, 1840.

DR. CLENDINNING IN THE CHAIR.

Pendulous Tumors of the Labium.

MR. CHARLES HAWKINS exhibited a specimen of several pendulous tumors which had been removed from the labium of a female by operation. They were composed of thickened integument and condensed cellular membrane, infiltrated with serum. When cut into, the fluid, with which the cellular membrane was loaded, gradually oozed out, causing the tumors to collapse and be corrugated. They had taken three years to grow, and did not give rise to pain till three weeks ago, when one of them became inflamed, grew harder, and finally ulcerated, discharging a thin ichorous fluid. The pain was of a severe lancinating kind. Upon their being removed at their common base, by the knife, only one vessel required to be tied.

Dr. Clendinning remarked that the tumors appeared to resemble, in structure, the enlarged growths in the same part found in the Hottentot females.

Coagulum in the Femoral Vein.

Mr. Hawkins drew attention to a preparation of clot contained in the right femoral vein. It was removed from a young man who had fallen from a height of fifty-two feet, and suffered fracture of his right thigh-bone. Several ribs were also broken; and he had the symptoms of fracture at the base of the skull. In three days from the accident, mortification was observed to commence in the right lower extremity. It proceeded, and he died from the effects of the mortification, and the other severe injuries. Upon dissection, a firm fibrinous clot was found plugging the right femoral vein near the seat of the fracture.

Mr. E. Wilson observed that it was not the common result of a coagulum filling the principal vein of an extremity for mortification to take place in the limb. He considered that, in the present case, the clot was formed in the vein as a consequence of the mortification produced by the severe injury, as it is invariably found that, when mortification occurs, the blood-vessels become filled with coagulum.

Calcareous Deposit on the Mucous Lining of the Bladder.

Mr. Hawkins placed upon the table some portions of triple phosphate of lime that had formed in layers upon the mucous coat of a diseased bladder. The patient,

twenty-one years of age, had suffered severely for three months preceding his death, in passing his water. Fragments of calculus, like the specimens on the table, were, at various times, passed by the urethra; and these sometimes had to be removed by the forceps, owing to their becoming impacted in the urethra. The only relief he obtained was from injecting his bladder with tepid water. If the catheter used for this purpose was allowed to remain for any time, it became thickly encrusted with calcareous deposit. Upon dissection, extensive disease was discovered both in the bladder and prostate gland, and in the kidneys—more particularly the right. The right kidney was sacculated, and contained a remarkable number of cysts, varying in their size from that of a pea to that of a walnut. The pelvis and infundibula were filled with a thin purulent fluid like a mixture of chalk and water. The ureter was considerably dilated. The left kidney was not so much diseased as the right: it was enlarged—of a red purple colour, approaching to black in some places, thus presenting a contrast with the right, which was of a light brown colour. The bladder was found to be reticulated in its muscular coat, to be greatly thickened, and to have numerous sacculi, formed by the protrusion of the mucous coat between the muscular bands. One of these sacculi was so thin, being lined exteriorly by the peritoneal coat alone, that it burst in the removal of the bladder. The peritoneal coat was observed to be highly inflamed. The prostate gland was much disorganized, its ducts being enlarged to such a degree as to present the appearance of a series of sacculi of different sizes. What attracted principal attention, was finding an extensive deposit of calcareous substance on the mucous coat of the bladder, forming the specimens on the table. When examined carefully, this deposit was seen to be disposed in layers, and to consist of distinct crystals chiefly composed of triple phosphate of lime. There was much ropy mucus, of a bloody colour, in the bladder.

Mr. Perry observed on the acute pain attending cases of calculus formed of the triple phosphate. He related a case that had come under his observation, where the most intense suffering was felt; and, on dissection, three small calculi, composed of triple phosphate of lime, and smooth on their outer surface, were found: the bladder was so free from disease that it might almost be considered healthy. On consultation with Dr. Prout, that gentleman expressed the same opinion as to the severe pain that accompanies the formation of this kind of calculus, even when unattended with much disease in the bladder, or roughness in the calculus itself.

Mr. E. Wilson made some remarks on the mode in which the calcareous substance in question is deposited on the bladder. To illustrate the subject, he gave the description of a dissection which he had recently made. It was in a case of cancer, involving nearly all the parts within the pelvis. A fungoid tumor projected into the bladder, so as to occupy the greater part of its cavity, and completely change the structure of its coats. What he principally begged to draw attention to, was the formation, on the surface of this tumor and the diseased coats of the bladder, of a thick crust of calcareous matter of the nature of triple phosphate. He considered that fibrine or lymph was first thrown out on the surfaces referred to, and that the calcareous substance was deposited within this lymph.

Mr. Hawkins observed, in reference to what Mr. Wilson remarked, that, in the specimens on the table, no appearance could be detected of any nucleus of an animal nature within the layers of calcareous matter.

Mr. Phillips was unprepared for the opinion expressed by Mr. Perry, as to the pain arising from the formation of a triple phosphate of lime calculus being greater than that produced by any other. From the observations he had been enabled to make, when a pupil of the Bristol Infirmary, where, with the exception of Norwich, calculous diseases were perhaps more frequent than in any other town in England, he was led to consider, that no pain could be greater than that occasioned by the mulberry calculus.

Dr. Clendinning remarked, that in regard to the severity of the pain occasioned by a stone in the bladder, two things were to be remembered, independently of the diseased condition of the bladder. First, the degree of pain will be influenced by the mechanical form and structure of the calculus; and, secondly, if the patient's constitution be broken down, he will have a greater susceptibility to suffering.

Dr. H. Lee suggested, that, in considering the question of pain, more importance ought to be given to the condition of the urine. When highly acid, the suffering of the patient was known to be aggravated.

Dr. Hodgkin coincided with many of the remarks that had been made. It appeared to him, that the very form of the mulberry calculus offered an argument against the pain attending its formation being so great as that in the formation of the triple phosphate. When the bladder contracted and emptied itself, in the case of a mulberry calculus, the pain was undoubtedly intense, owing to the inner coat of the bladder being brought into forcible contact with the rough, jagged surface of the stone. But if the bladder were much

inflamed in these cases, and, on account of the irritation caused by the inflammation, contracted for any length of time upon the calculus, it is reasonable to suppose that the surface of the stone would be smooth, instead of being rough and spiculated, as is the case in the mulberry calculus. Hence he considered that the bladder did not contract so habitually and constantly on the mulberry calculus as on that formed of phosphate of lime, which is always smooth on its surface. The latter kind of calculus, unlike the mulberry calculus, depends for its formation on the diseased condition of the coats of the bladder, and not so much upon the peculiar composition of the urine secreted by the kidney: He was further anxious to draw the attention of the society to an interesting circumstance mentioned in the narration of the case. One ureter and one kidney were more changed in their structure than those of the opposite side. What was this owing to? He conjectured, (for it could not be further determined, as we had not the bladder before us), that the disease was greater in the kidney of the right side, in consequence of something obstructing the ureter on that side more than on the left. It may have happened, that a sacculus of the bladder may have been formed in such a situation as to close the orifice of the ureter, where that duct pierces the coats; or a portion of the calcareous deposit may have been lodged in such a manner as to produce the same effect; the passage for the left ureter being comparatively free. He next begged to make a remark on the cysts found within the substance of the kidney that was principally diseased. These cysts, he was led, from frequent examination of them, to regard as dilated tubuli uriniferi. He conceived that they were formed from the tubes in question, being in the first place obstructed some where in their course, from their continuing to secrete a peculiar fluid; and this fluid, by its accumulation, finally distending them into the form of thin sacs. That the fluid found in the cysts is of a bland limpid nature, different from urine, does not militate against the idea here broached. When the ducts of the liver are obstructed; for example by the fungoid tumor so frequently found in that viscus, they become greatly dilated; and the fluid with which they are filled, instead of possessing the characters of true bile, consists merely of a clear serum. A similar change in the nature of the secretion naturally poured out from the gland, he believed, is to be observed in the testis, when the vas deferens is obstructed.

Diseases of the Heart.

Dr. Clendinning exhibited in a preparation, two portions of a heart affected with hypertrophy and disease of the aortic valves. The walls of the left ventricle were

much increased beyond their natural thickness, and the semilunar valves of the aorta were also thickened, so that they did not close perfectly. The patient was the subject of a complication of disorders, some of which were referable to the brain, others to the heart and contents of the thorax generally. Her age was thirty-five. Previous to her becoming Dr. Clendinning's patient, in the Marylebone Infirmary, she was under the care of the late Dr. Sims, between February and August, 1838, for cough, and certain convulsive fits. She was relieved by the treatment; left the Infirmary; but returned, with a recurrence of her complaints, in September 1838; when she was placed under Dr. Clendinning's charge. On examining the head, nothing was found but a preternatural enlargement of the tubercle of the occipital bone, which the patient insisted was the seat of certain uncommon sensations; such as of water flowing in it, and causing it to enlarge and decrease in size. In the chest, the indications of hypertrophy of the heart, combined with valvular disease, were found; together with those of emphysema extensively diffused over the lungs. The limbs were anasarous, and there was dropsical effusion in the abdominal cavity; the urine was albuminous. The fits to which she was subject resembled those of epilepsy in some degree. They varied remarkably in the period of their occurrence; sometimes in one day she had as many as forty distinct attacks. The patient was under Dr. C.'s observation for eighteen months, and she continued to have the fits until three months before her death, which took place in March last, owing to an attack of acute pericarditis.

On dissection, nothing preternatural was found in the brain, except that as a whole, it seemed larger than natural; that is to say, the convolutions met more closely than is usual: and the ventricles had their sides compressed, so as to allow of no fluid between them, and its weight was equal to that of the standard brain in the male sex; presenting, in short, all the characters which Dr. C. recognizes as constituting hypertrophy of the brain. The lungs were emphysematous throughout the greater part of their extent. The condition of the heart has been already described. The kidneys presented the appearances described so admirably by Dr. Bright; one of them exhibiting the structure usually seen in the first stage, and the other the structure belonging to the last stage of the disease, which gives rise to the formation of albuminous urine in cases of anasarca. Dr. Clendinning concluded, by making numerous interesting observations on the principal phenomena noticed in the case; for which we regret we have not space.

EXAMINATIONS AT THE COLLEGE OF PHYSICIANS.

THE Censors of the Royal College of Physicians present their compliments to the Editor of the MEDICAL GAZETTE, and, as they consider it highly desirable that gentlemen, who are about to offer themselves as candidates for the licence of the College should be apprized of the nature of the examinations they will have to undergo, transmit for insertion, in the LONDON MEDICAL GAZETTE, the accompanying papers.

P. MAYO	} Censors.
R. BRIGHT	
G. BURROWS	
R. B. TODD	

FIRST EXAMINATION.

IN PARTE PHYSIOLOGICA.

April 1840.

1. Describe the situation of the heart, in the normal condition, specifying its relations to the walls of, and the other viscera contained in, the thorax.

2. On what does the phenomenon of the arterial pulse depend?—State the average number of beats in a minute in health, in childhood, adult age, and old age; and mention such circumstances as may give rise to variations in the frequency of the pulse.

3. What are the constituents of the blood? Explain what is meant by buffing and cupping of the blood? State the circumstances under which this phenomenon occurs, and account for it?

4. State what you understand by "valvulae conniventes," "Brunner's glands," "Peyer's glands," "glandulae solitariae?"

5. Describe the origin, course, and distribution of the "portio dura" of the seventh pair of nerves.

6. Describe the structure of the kidneys. What are the "corpora Malpighiana?"

7. Enumerate the intrinsic muscles of the larynx. Specify those which close the glottis. Describe the distribution and functions of the superior and inferior laryngeal nerves.

TRANSLATE INTO LATIN.

A'. Αἱ μεταβολαὶ τῶν ὥρων, μάλιστα τίκτους νοσήματα, καὶ ἐν τῇσιν αὐτέσσι ὦρσι αἱ μεγάλαι μεταλλαγαὶ ἢ ψύξης, ἢ θάλλψος, καὶ τάλλα κατὰ λόγῳ οὕτω.

β. Τῶν φύσεων, αἱ μὲν πρὸς θέρους, αἱ δὲ πρὸς χειμῶνα, εὖ ἢ κακῶς πεφύκασι.

γ'. Καὶ τῶν νοῦσαν ἄλλα πρὸς ἄλλας εὖ ἢ κακῶς πεφύκασι καὶ ἡλικίαι τινὲς πρὸς ὥρας, καὶ χώρας, καὶ διαίτας.

δ'. Ἐν τῇσιν ὦρσι, ὅταν τῆς αὐτῆς ἡμέρας, ὅτε μὲν θάλλπς, ὅτε δὲ ψύχος γίνηται, φθινοπωρινὰ τὰ νοσήματα προσδέχεσθαι.—HIPP. Aphor. 1, 2, 3, 4. Sect. iii.

TRANSLATE INTO ENGLISH.

[A passage from Heberden's Comment. p. 321., which lack of space compels us to omit.—ED. GAZ.]

SECOND EXAMINATION.

IN PARTE PATHOLOGICA.

April 1840.

1. Describe the formation of an abscess, and the process by which the pus makes its way to the surface of the body.

2. Contrast the symptoms of phrenitis with those of acute delirium tremens.

3. Describe the symptoms of cynanche trachealis, and the lesions of structure induced by that disease.

4. What are the early symptoms of pericarditis, and those which indicate that the inflammation has terminated in hydrops pericardii?

5. Enumerate the various causes which may induce icterus, and the symptoms occasioned by the passage of biliary calculi.

6. What are the symptoms of intus susception, or stangulation of a portion of intestine?

7. Describe a case of diabetes mellitus. In what fluids of the body may the saccharine matter be detected?

8. Describe scarlatina maligna, and the most frequent sequelæ of that disease.

TRANSLATE INTO LATIN.

[An extract of considerable length, from Thucydides Historia, Lib. ii. 49, which want of space compels us to omit.—ED. GAZ.]

gunt.—*Lucretii*, lib. iv. 333.

THIRD EXAMINATION.

IN PARTE THERAPEUTICA.

April, 1840.

1. State the leading indications in scarlatina maligna, and the measures appropriate under each head.

2. State the circumstance under which bark, colchicum, opium, and calomel, are respectively or conjointly indicated in acute rheumatism.

3. State the inducements and objections to puncturing the thorax in presumed empyema or serous effusion.

4. State the treatment indicated in icterus, where there is acute pain in the right hypochondriac region, and obstinate sickness. Describe the appropriate remedies.

5. Describe the measures indicated in pneumonia, when hepatization is presumed to have occurred.

6. State the process which takes place in the formation, according to the Pharmacopœia, of tartaric acid.

7. How is strychnie prepared? What are its uses, and doses?

COLLEGE OF PHYSICIANS'
DEGREES.

To the Editor of the Medical Gazette.

SIR,

IN the last number of your journal you have inserted the letter of a correspondent, in which it is asserted that the London College of Physicians "can and do grant the degree and title of Doctor of Medicine to those who pass examinations for licentiates or extra-licentiates, whether they have obtained degrees elsewhere or not; and that the College possess this power by as clear and legal right as any university in the kingdom." Your correspondent has given no reference to the authorities on which this statement is made; and as he has chosen to conceal his name, he will not, of course, expect that his mere *dictum* will satisfy those who feel an interest in knowing the truth. About a year ago it was my intention to submit myself to the examination for the license of the College, and I decided against this step chiefly because I could find no reason for believing that the College possessed a right to confer the title of Doctor. The following extracts from the evidence given by Sir H. Halford, in the year 1834, before the Committee of the House of Commons on Medical Education, seem to me very clearly to imply that the President believed the College had not the power to give degrees. After stating his opinion that there should be in London some authority empowered to grant Medical Degrees, he is asked, *Quest. 314.* "What is the constitution

that you are disposed to recommend for such a board or body, empowered to grant degrees? *Ans.* It appears to me that the best and most effectual of the plans proposed would be to give the College of Physicians the power of granting that medical distinction; for from whatever part of the world persons come, they have no right to practise without the sanction of the College. When the College has granted its license, let it have the power of granting also the title." In his answer to another question of similar import (319), Sir Henry says, that the College, if they choose, may say to an applicant—"We will not expect a degree, but only certificates of attendance on certain lectures; we will then examine you; we will not ask for a degree;" but he adds, "What are we to call him when we have examined him? *We cannot call him Doctor*; though he is from thenceforth M.D. to all intents and purposes." Again, *Quest.* 340. "The effect of the plan proposed (by Sir Henry) would be merely this: that the College should attach the title of *Doctor* to the licentiate whom they examined and approved?" *Ans.* "Precisely."

I believe I have somewhere seen the statement, though I cannot now refer to it, that the College, before this evidence was given, presented a petition to the King in Council, praying for the power to confer degrees, and that the object sought for in that petition was refused.

I am not aware that any additional powers have been given to the College for many years past, and yet, in an address to the profession, dated December 1838, they state that they are willing to do that which Sir Henry has mentioned in one of his answers, viz. to license those who have passed through the course of study prescribed by them, whether they previously possessed degrees or not; and in the face of the President's statement—"We cannot call him Doctor," the College "is prepared to regard in the same light, and address by the same appellation, all who have obtained its diploma, whether they have graduated elsewhere or not." The meaning, rather insinuated than boldly spoken, of this sentence being, of course, that the College will give its licentiates the title of M.D. or Doctor of Medicine, and will authorize them to assume the same.

Having consulted the Charter and Acts of Parliament in virtue of which the College exercises its powers, I can find nothing in them to justify the belief that the privilege of giving degrees was intended to be conferred on the College; and I believe that the College never attempted to exercise such a power, before it became likely that another body in London would be authorized to grant degrees.

As I presume from your insertion of the letter which has suggested these observations, as well as from various notices of this subject which have appeared in your journal, that you think the question here discussed one of some importance for the profession to be accurately informed upon, I trust you will find room for these remarks. If they satisfy those whose interests are concerned, that the College do not possess the powers which they claim, or if they induce some one better acquainted with the subject to show by what authority the College can legally claim such powers, I shall, in either case, be equally contented.

I am, sir,

Your obedient servant,

JOHN TAYLOR, M.D.

Of the University of London.

University College Hospital,
April 23, 1840.

BEING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

FRIDAY, MAY 15, 1840.

LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

DISEASES OF FIBROUS TISSUES.—*Inflammation of the Periosteum—Nature—Symptoms—Varieties—Treatment.*—DISEASES AND INJURIES OF OSSEOUS TISSUES.—*Wounds of Bone—Fractures—Nature—Varieties—Symptoms—Prognosis.*

PERIOSTITIS.

INFLAMMATION of the periosteum is a disease of more frequent occurrence than is generally supposed. I believe that many cases of severe deep-seated pain, deemed rheumatismal, might with more propriety be referred to inflammation of the periosteum. The disease may be acute or chronic, may end in suppuration, (and this is the severest form, as is well exemplified in certain cases of paronychia,) or in the deposition of cartilage or bone.

It may be occasioned by a great variety of causes; contusions, local irritation from contiguity of ulcers, wounds, operations in which the periosteum is implicated, amputations for example, fractures, deep-seated phlegmonous inflammation; all these affections or injuries may determine the development of periostitis; but these exciting causes seem to act with as much more certainty as the system may be impregnated with scrofula or syphilis.

Whatever may be the cause of periostitis, it is manifested externally by very similar symptoms, the variety depending upon the kind of inflammatory action, whether acute, chronic, or suppurative. If the inflammation be limited to the thickening of the periosteum or to the deposition of cartilaginous or bony matter, the symptoms are often very mild, but when it ends in

suppuration, they are often extremely severe. Insensible in the healthy state, it acquires, when inflamed, a very acute sensibility; and this is more particularly marked when suppuration has set in. On the one hand the bone resists, on the other the periosteum does not yield, and the agony the patient experiences is intense.

At first the severity of the pain is variable, usually the most severe at night; there is slight tumefaction, puffiness or œdema; the tumor increases, and assumes an elastic or doughy feel. As the pain becomes severe, violent sympathetic disturbance is often excited, and this is as much more intense as the part affected is nearer the brain.

Anatomically considered, it may be divided into stages. In a first, the membrane is more or less richly injected; it is thickened, infiltrated with serosity, and is less adherent, than in its healthy state, to the surface of the bone. Generally the adjoining cellular tissue and soft parts participate in this state of injection and infiltration. This appearance is usually seen when chronic ulcers or old cicatrices are in its immediate vicinity. In another stage the periosteum is thicker and denser, of a red colour, and much increased sensibility. This is its condition during the formation of callus, and the regeneration of necrosed bone. Then also the periosteum is evidently injected, tumid, and bathed in a gelatinous reddish fluid, susceptible of coagulation, and of undergoing organic changes. Still further we arrive at a condition destined to produce organized matter; we see it form a new osseous tissue, which incrusts, as it were, the primary tissue, so as to form a species of osseous vegetation. If in this stage, the disease becomes chronic, the thickened periosteum is more dense, and may assume a coriaceous or ligamentous character. Its adhesion to the bone at this time is very strong, and when we detach it, we perceive at its surface longitudinal furrows, which give to its cortical substance a fibrous appearance

similar to that of the bones of the fœtus. If the inflammatory action become more intense, the periosteum is more thickened, and assumes somewhat the appearance of a mucous membrane. It is thus we find it when it is in contact with an abscess, or when there is pus between it and a bone. Under these circumstances its nature and functions are changed; instead of furnishing a plastic organisable lymph, it secretes a peccant matter capable of injuring parts with which it is in contact. As the disease proceeds, the bone suffers, and becomes carious or necrosed; the periosteum is softened, and ultimately destroyed.

In the Dublin Hospital Reports, vol. i., page 331, Crampton describes the case of a lad of fourteen, attacked with erysipelas of the nose, and who died on the twelfth day from the attack, with symptoms of inflammation of the brain. The examination after death showed the periosteum covering the nasal and frontal bones thicker than usual, and of a deep red colour; it was separated from these bones as well as those of the orbit, a greenish peccant matter being found between it and the bones. The brain was injected, and a part of the pia mater was in a state of suppuration, at a point precisely corresponding to that where the dura mater was thick and livid.

In the next form, the disease rarely determines such fatal accidents, however severe the pain which accompanies it may be, because it occasions a change of tissue or a new product. A woman of 32 was struck with a boot-hook on the left side of the head, which produced a momentary stunning sensation; the soft parts had not been much hurt, and her health was not interfered with. Six weeks after the accident a small painful tumor was developed at the spot; the pain gradually increased, and was accompanied by headache, nausea, and sleeplessness. After some time, an epileptic attack occurred, which was followed by paralysis of the right arm, and a defective articulation. Six months after the accident she was admitted into the hospital, complaining of pain at the right side of the head; the countenance bore evident marks of suffering; the right arm was atrophied, and the fingers spasmodically contracted; station was almost impossible, speech was difficult, the stomach rejected food, and the bowels were obstinately constipated. A second epileptic attack occurred on the day of her arrival at the hospital. The centre of the left parietal bone presented a tumor of the size of a small walnut, hard at its circumference, soft and elastic at its centre, and pierced by a small opening which admitted a sound to pass to the bone. An incision was made, and it was discovered that the tumor was formed by the pericranium, which was changed into a very vascular,

extremely sensible, fibrous tissue, firmly adherent to the bone. A crown of a trepan was applied; the piece of bone removed was rough, and the dura mater bled freely. Nine days passed in paroxysms of delirium, coma, and convulsions. Erysipelatous inflammation followed, with copious suppuration, and exfoliation of a portion of dura mater. The patient got quite well, having recovered the use of her right arm. Now if, instead of altering the pericranium and the bone, the inflammation had been suppurative, the consequences would probably have been fatal.

There are regions of the body subject to fewer accidents when they are the seat of periostitis; such is particularly the internal surface of the tibia. Crampton mentions many curious observations of this kind. A young man of 25 had severe pain along the internal surface of the tibia, without tumefaction or change of colour of the skin; he had besides intermittent fever. Three longitudinal incisions were successively made along the painful parts, and down to the bone. The pain, which had been momentarily lessened by the first two, did not entirely disappear until after the third was made. The periosteum was a quarter of an inch thick, of the consistency of cartilage, and extremely sensible. In a second case, a woman of 25 had on the right tibia, two inches above the ankle, a very painful tumor three inches long, soft and elastic, the colour of the skin unchanged, but with a slight subcutaneous serous infiltration. Repeated applications of leeches weakened the patient, without procuring the slightest relief. Incision down to the bone radically cured the disease; the periosteum was thick, and similar to a ligamentous expansion.

A fourth and equally instructive case is that of a young man of 26, who presented an extremely painful, ill-circumscribed tumor, on the inner side of the tibia. The patient, who had had no sleep for twelve nights, said, he had suffered similar pain, at the same point, two years before, for which leeches and blisters had been used, without relief. A caustic issue had given him some relief, but the pain was not dissipated until the escape of a small spicula of bone. An incision, three inches long, was now made, penetrating to the bone, and occasioning a good deal of pain. The hæmorrhage was considerable; but, during the night, the pain ceased, and the patient was soon cured. The next year the same leg was affected lower down; the same treatment was followed by complete success. Now, in neither of those three cases was there any trace of purulent matter either above or below the periosteum.

SYPHILITIC PERIOSTITIS.

The most frequent cause of periostitis is, I apprehend, syphilis. It begins by obtuse

periodical pains, which have this peculiarity, that they are generally very distressing at the break of day. The affected parts are very sensible upon pressure, even when a bone is deep-seated. After a time the patient gets little or no sleep, becomes emaciated; the pulse is small and frequent, depending less, perhaps, on fever, than on nervous irritation.

If, after death, we examine the affected bone, we find the periosteum thick and vascular; the surface of the corresponding bone has no longer that smooth, bluish aspect, which is so characteristic of it in its natural condition, but is unequal, and slightly spongy. Nothing, however, is extravasated between the membrane and the bone, and they are perfectly adherent the one to the other. If we dry the bone, it will be found to present points where the natural appearance and colour are lost, and where dark, alternate with light spots.

Whether the disease has originated in the bone or the periosteum I shall not stop long to inquire. Hunter thought the bone first suffered; but if we attend to the seat of the pains, and the organic changes which occur in the membrane, I think we shall come to the conclusion that the periosteum is the first implicated.

When the pericranium is the seat of the disease in syphilitic patients, it is marked by certain peculiarities. It is sometimes extremely transient. The patient, when he awakes, feels certain inequalities, superficial bumps, painful to the touch, and sometimes accompanied with circumscribed redness. At other times the disease proceeds more slowly, is more obstinate, and occupies a greater extent of the cranial surface. In some cases the pericranium has been found thickened down to the foramina, through which the nerves pass, exercising compression upon them, and producing pain or paralysis in the parts where they are distributed. This state of the cranium is not, however, always the result of a syphilitic infection.

There is a condition of the periosteum, probably of an inflammatory nature, under the influence of which certain tumors are developed. These tumors differ in their consistence, their nature, their origin, their progress, and termination. Some are formed of a thick syrupy fluid; others are hard and cartilaginous; others very apt to ulcerate; others disposed to soften.

Nodes are hard, ill circumscribed tumors, seated particularly upon those bony surfaces which are very superficial, such as the cranium and the tibia; still they are observed also at the bones of the elbow, the ribs, the clavicle, the fore-arm. In size, they vary from that of a cherry-stone to that of a walnut, or even of a hen's egg. In many cases their contents are not un-

like, in colour and consistency, to the pulp of red gooseberries. Their seat is either the periosteal tissue, or between it and the bone, the surface of which commonly remains smooth. Each of these tumors is exactly circumscribed; and, when there are many on the same bone, as sometimes happens in the cranium, they are not confluent, however near to each other they may be. In these cases the periosteum does not present any considerable change of texture or colour; the cellular tissue, external to it, is a little infiltrated with serosity. The extravasated fluid is tasteless and inodorous, and has no acrid character. As to the symptoms which ordinarily accompany these tumors, they are usually preceded by more or less acute fixed pain, most severely felt during the night. For this, a reason is not easily assigned.

Another form of this affection is presented, distinguished by the hardness of the tumor. At first fibrous, it degenerates into a fibro-cartilaginous, and afterwards into an osseous tissue. If we divide with a saw a bone so affected, an osseous reticular mass is found to be developed between the periosteum and the bone, and adherent to both. This affection, to which Sir A. Cooper applied the term cartilaginous periosteal exostosis, is particularly developed in long bones, especially along the inner border of the femur, and that of the tibia. It increases slowly, and is not accompanied by violent pain. It seems probable, that it is caused rather by external violence, than by constitutional means. Though this condition may not be malignant, it may remain during life completely indolent.

There is a third species, which consists in a fleshy tumor, developed in the substance of the periosteum. In size it is variable; in consistency not unlike the prostate gland; homogeneous, and for a short time indolent. If inflammation set in, and the skin quickly participate, they become quickly adherent, inflame together, an abscess is formed, spontaneously opened at several points, and a moderate quantity of pus escapes, but the tumor does not lessen.

Another variety exists, in which the periosteum and the cellular tissue, which corresponds to its external surface, are transformed into a homogeneous, whitish, or greyish, tolerably compact substance, a section of which resembles an inflamed lymphatic gland. This substance may soften, become vascular, and ultimately degenerate into medullary matter. It is this variety to which Sir A. Cooper has given the name fungous periosteal exostosis, and which he describes as a lobular tumor, composed of a white elastic substance, alternating with a softer and more vascular portion. He believes it to possess malign-

nity, since it is seen in persons whose constitution is bad, increases rapidly, and is accompanied with pains which coincide with the progress of the disease. A very slight examination suffices to recognise essential differences between these four species of periostosis. The first consists in a simple collection of a viscous fluid, without change in the parts with which it is in contact; the second is a fibro-cartilaginous tumor, degenerating into an osseous tumor, and gradually identifying itself with the bone; the third is a mass susceptible of ulcerating; the fourth is a substance at first dense, but degenerating into medullary matter.

Treatment.—In the treatment of uncomplicated acute periostitis very energetic means must be employed. Local and general bleeding frequently repeated, and counter-irritation, with absolute rest, must form a principal feature. As the acute symptoms abate, mercurial and iodide remedies will be found useful; but, in a great majority of cases, more relief will be derived from freely laying open the part than from any other means; and this is so much more easily done, as the affected bone is in the greater number of cases superficially placed. I speak here of cases in which we have no reason to believe that any syphilitic contamination exists; where the disease is complicated with syphilis, we shall speak of its treatment hereafter.

INJURIES OF BONES.

Wounds.—In speaking of the soft parts, the word wound signified all kinds of solution of continuity produced by external causes; but, in speaking of bones, we use it in a more restrained sense: we then apply the term to a solution of continuity produced by a cutting instrument. We apply the term fracture to solutions of continuity produced by rupture.

It is in the bones of the cranium that wounds are most frequently seen. Not many weeks ago I saw a case where, by a blow made with the edge of a flat iron, a fair incision was made in the external table of a man's skull to the extent of an inch and a half; the lips of the wound were not sensibly depressed. From analogy we might say that wounds of bone, produced by a cutting instrument, would unite much more easily than a fracture. Lamotte mentions a case where a sabre-cut completely divided the inferior part of the ulna, and where the wound was, he thought, twice as long in healing as a compound fracture would have been. A cutting instrument almost always produces a certain quantity of contusion to the bone, the periosteum is more or less injured, and partial caries or necrosis may happen. Lamotte certainly exaggerates

the inconvenience of such injuries—a finger fairly cut off will completely unite in a comparatively short time.

Union should certainly be attempted when the parts are held together by a moderate flap. Lafaye, in his notes to the operations of Dionis, says that Lapeyronie had to treat a man who, with a blow of an axe, had his arm cut through, with the exception of a portion of the soft parts which contained the principal vessels: he attempted to save the limb, and succeeded. Stevenson succeeded in uniting an arm which had been almost completely separated by a sabre cut. In that case not only the bone, but the biceps muscle and the artery, had been divided (Edinburgh Med. and Surg. Journal, July 1837.) Indeed, with respect to the power of nature to repair injuries of this kind, it is difficult to place limits. We must not heedlessly reject the marvellous, because between established fact and convicted fiction there is much to be gleaned. I should have a difficulty, for instance, in admitting as fact a case narrated by Job a Meckren. A nobleman had a part of his skull sliced off by a cutting instrument; the bone was not forthcoming, and the surgeon imagined that he could borrow a piece from a dog's head which might answer the purpose of an obturator. The poor dog had to submit to the operation necessary to procure a piece of cranium of the proper size: it was applied upon the noble's head, and perfectly united. The priests of the time, scandalized by seeing on the head of a Christian a portion of the skull of a dog, excommunicated the unfortunate gentleman for the purpose of compelling him to purge himself of the scandal which had been done. Still this circumstance loses much of its marvellous character when we recollect the graftings and transplantings of Hunter—the experiments of Merrem and of Walther, who removed discs of the cranium which were replaced and united by bony matter. In 1802, Maunoir proposed to replace the discs which had been removed by the trepan for the purpose of evacuating fluids. This was objected to because it was alleged that these discs continued to be foreign bodies which did not enter into organic union. Walther opposed to this the following fact:—one of these discs was replaced in the point from which it had been taken, the external table of this disc exfoliated, and exposed the inner table covered with granulations—a conclusive proof that organic relations had been established. A bone perpendicularly and completely cut through is susceptible of union without exfoliation, provided the soft parts which surround it are brought together and preserved from

suppuration. But these injuries, when considerable, must be treated like fractures by such an apparatus as will most effectually preserve the part from motion.

Whatever may be the direction of the wound, it remains for a time in the condition in which it is left by the instrument; there is no elasticity or immediate tumefaction, as in the soft parts, by which the edges are approximated. When a piece is fairly cut out with the soft parts, as in certain sword-wounds, the wound must be dressed like an ordinary wound with loss of substance, unless so fairly or recently cut as to admit of being brought into immediate apposition.

FRACTURES.

A fracture is a partial or complete destruction of continuity in a bone by rupture; and it is an accident which, from the frequency of its occurrence, the varieties which it presents, the serious symptoms which it sometimes excites, the complications by which it is often attended, and the general efficacy of well-directed modes of treatment, demands our most serious attention. As might naturally be expected, fractures are more frequent in long than in short or flat bones. Those long bones which form the great levers of locomotion, and which are destined to sustain considerable exertions, are most frequently the seat of fracture. Though a fracture may occur at any point in the continuity of a bone, the middle, which is at the same time the thinnest part, is most exposed to it. A bone may be fractured at more than one point; this is often the case in the ribs.

Varieties.—Much variety exists in the nomenclature of fractures. Thus, in France, a *simple* fracture affects only one bone without much injury to the soft parts. A *compound* fracture exists when two bones composing a limb are fractured, or when one is fractured at more than one point. When there are many fragments, it is termed a *comminuted* fracture. When it is accompanied by other diseases or injuries which render the treatment long or difficult, it is termed a *compound* fracture. In England, we follow a somewhat different course. We are satisfied to make two great classes—the *simple* and the *compound*. By a *simple* fracture we understand a destruction of continuity of a bone without any external wound to form a communication between the fractured bone and the exterior. By a *compound* fracture we understand a similar injury to the bone, but accompanied by such a destruction of the soft parts as will establish the communication which was wanting in the former class. We use still other terms of

distinction. We call a fracture *complicated* when it is accompanied by some other disease or injury which may complicate the treatment.

Although Boyer rejected the idea, yet there can, I think, be no doubt that the opinion of Meding, Chelius, Marjolin, and Campagna, is correct. They maintain that a fracture may be incomplete; that it may affect one side of a bone and not the other. The accompanying sketch, taken from a specimen in the museum of the faculty at Paris, is conclusive as to the occasional occurrence. It is produced, I

apprehend, in the same way that such an appearance may be produced in a hazel stick by bending it over the knee: bending is unquestionably necessary for its production, and, therefore, it is most likely to happen in children or young persons. Again, a bone may be fractured *transversely*, or *obliquely*, or even *longitudinally*. Duverney mentions three such cases. Petit and Louis seem to deny the possibility, because, they say, no blow is capable of fracturing a bone in this direction. Nevertheless, it is not an uncommon accident as a consequence of gun-shot, nor, indeed, from other causes. Thus, in a fall from a height, the head of the tibia may act the part of a wedge, and split up the femur between the two condyles. Such a case is mentioned by Cloquet, in which the fracture extended to the lesser trochanter. In 1800, Leveille amputated, at Marengo, the leg of an Austrian soldier, in whom there was a longitudinal fracture, extending from the lower third of the tibia to the knee-joint. Samuel Cooper and Cole mention several similar cases from gun-shot.

Causes.—A fracture may be produced by the application of violence directly upon the point or at a distance: but there are many circumstances which seem to predispose to it. Thus the situation of certain bones, and the functions they fill, more particularly expose them to fracture. The

radius, which supports the hand, is more frequently fractured than the ulna; the clavicle, which supports the arm in the motions upon the trunk, frequently suffers. Again: age, by lessening the proportion of the animal to the earthy matter, increases the fragility, and causes a greater frequency of fracture in age than in youth. Still it is not this circumstance alone which explains the greater frequency of fractures at this period of life: the muscular system is enfeebled, their step is less assured, and falls more frequent. That certain diseases cause fragility is unquestionable: among these we usually rank cancer, syphilis, scorbutus, gout. Benjamin Bell and Meckren mention cases where, in persons affected with syphilis, muscular action alone has served to cause fracture. As evidence of the influence of gout, Fabricius Hildanus mentions the case of a person, aged 60, who broke his arm in putting on his glove; but the details shew that there was also caries. The influence of cancer is better established. Desault, Louis, Cooper, mention cases of this kind. I think, however, that the effect is

most decidedly shewn in those bones most directly connected with a carcinomatous deposition. Rickets sometimes renders the bones more fragile, at others more elastic. We have seen cases where fractures occurred under the slightest causes. Esquirol has the skeleton of a woman who was a martyr to rachitis, in which nearly every bone is covered with traces of fracture; altogether they amount to more than 200. Scorbutus is also a predisposing cause; and in all these cases, the predisposing cause indisposes the fractured bones to unite. Many men have maintained the opinion, that bones are more brittle in cold than in warm weather: among others, A. Paré maintained this doctrine. In the present day, this idea is not so prevalent. That fractures are more frequent in winter than in summer, is perfectly true, but then falls are so also.

As we happen to have the register of 2328 cases of fracture admitted into the Hôtel-Dieu, furnished by Malgaigne, we will endeavour to ascertain the correctness of that and other opinions with respect to fractures.

	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.

If we divide the year into four quarters we get the following results:—

	1st Qr.	2d Qr.	3d Qr.	4th Qr.
1806 8	131	129	129	157
1830-33	262	193	187	214
1834-7	246	259	209	253
Total...	639	571	525	624

If we divide the year into three sections of four months each, we find—

	Dec. to March.	April to July.	August to Nov.
1806 8	193	166	187
1830-3	336	260	260
1834-7	338	332	289
Total...	867	758	735

The last table is most favourable to the influence of cold; and yet, if we take the four most wintery months, we see that the preponderance over those of spring is not more than an eighth, and even this is inconsistent, for if we take the four winter months of 1806-8, it scarcely exceeds those of autumn; and if we take the months of each season, January is, in one

case, inferior to June, once equal, and once superior; February is constantly inferior to June, and October and March are almost in the same situation. It is found, that though, as a general rule, a greater number of fractures occur in winter than summer, yet, three times in eleven years, the contrary has occurred.

The next questions to be considered here, are, why are fractures more frequent in winter than in summer—why is the preponderance so small, and why occasionally is the preponderance the other way? I think there can be no doubt that the greater frequency is owing to the greater frequency of falls, and not to any influence of the rigour of the season upon the fragility of bones.

Now as to age, if we divide life into periods of five years, and use the same registers, and seek for that in which fractures are the most frequent, bearing in mind that the registration does not include the two extremes of life, children below the age of two years not being admissible, and the cases of fracture above eighty being so very few, we shall find that the disposition to fractures is feeble from two to

five years; increases from five to fifteen; so that the third period more than triples the first, the fourth triples the third, and the increase during the long period comprised between twenty-five and sixty, is only a fourth: from sixty to seventy the decrease is a fourth; a third from seventy to seventy-five, and a half from seventy-five to eighty; from eighty to eighty-five scarcely exceeds the first period. The age of predilection, as it were, is from twenty-five to sixty, a period of thirty-five years, or the half of life; it furnishes 1448 out of 2376 fractures, leaving only 888 for the other half. To be complete, however, it would be necessary to shew not only the proportion of fractures occurring in individuals of a given age, but what proportion the people of that age bear to the whole population. Now supposing we take 1,000,000 as the population, among whom the 2328 fractures occurred; we find that from 5 to 10 they are, comparatively, excessively rare; that the predisposition goes on increasing with age, not only from 15 to 25 and from 25 to 60, but every five years of that vast period, in fact, year by year up to 60; so that these two periods, from 25 to 30 and from 55 to 60, give nearly an equal number of fractures. Beyond 60, a very remarkable and an unexpected result appears: the proportion of fractures diminishes relatively to the population. The proportion

between 65 and 70 does really increase, but still not materially, because, for all practical purposes, the proportion is nearly the same from 55 to 80, whilst up to 55 it almost progressively increases. Above 80, the predisposition would seem, according to our returns, to diminish; but this may be only apparent, for, beyond 79, old people in Paris have a right to enter the two hospices, and the proportion entering the Hôtel-Dieu might naturally expect to be lessened. We may, therefore, sum up as follows:—We have little information about the two first years of life; frequent between 2 and 4; less so between 4 and 6; increase becoming tripled about 15; at 25 increased by a fourth, and continuing nearly the same up to 60, in spite of the annual decrease of the population. Between 55 and 80, the absolute number of fractures diminishes nearly in the same proportion as the population. Between the ages of 2 and 80, from 4 to 5 is the period when fractures are most unfrequent; from 55 to 70 most frequent.

We also find in inquiring what are the ages which furnish the greater number of fractures at particular seasons, supposing we divide the year into two periods, one comprising November, December, January, February, and March, the other May, June, July, August, September, and October, that in eleven years the following numbers are yielded:—

	2 to 15	15 to 25	25 to 35	35 to 45	45 to 55	55 to 60,	and above.
Winter.	47	126	224	208	225	422	8
Summer.	66	163	222	207	188	272	8

Thus we see that from 2 to 25 the proportion has been greatest in summer; from 25 to 45 it has varied, being sometimes greater in winter, sometimes in summer, being in mass nearly equal. From 55 to 70, summer has constantly yielded the smaller number of fractures, and the difference is so great that the preponderance in favour of winter is nearly half. This increase in winter is manifested from the age of 45, and it is from this period that anatomists have commonly dated the period of absorption.

As to sex, men are more subject to fractures than women; from my general total, I find 1679 to 680, or about $2\frac{1}{2}$ to 1, or 5 men to 2 women. Before 5, the female sex furnishes a greater number of cases than the male, but the proportion of males goes on increasing until between 15 and 20, when the preponderance in favour of the male is as 7 to 1; from thence it decreases until between 67 and 75, when the numbers are as nearly equal, and between 75 and 90 the preponderance is in favour of the female, nearly in the proportion of 2 to 1. Thus, at the two extremes of life,

the number of fractures is greater in woman than man.

The right limbs are fractured more frequently than the left by nearly a fourth. Out of the total of 2328 cases, 399 affected the trunk, 925 the superior extremities, 1024 the inferior.

In the Calcutta Quarterly Medical Journal, for January 1838, is a report by Mr. Martin, of 1572 cases, of which 193 affected the trunk, 680 the superior, and 699 the inferior extremities. Mr. Lonsdale, in his work on Fractures, gives the general results of 1901 cases of fracture presented at the Middlesex Hospital; 468 affected the trunk, 911 the superior, and 522 the inferior extremities. We have now indicated as clearly as we can the influence of season, sex, and age, in the production of fracture.

Direct fractures may be produced by falling on a sharp body, by a blow, or by a musket shot; if the bone be soft and spongy, the foreign body may more or less completely traverse the bone, and the fracture may not extend beyond the point; but if the bone be hard and compact, it may be splintered, and the fracture may extend to some dis-

tance; thus, if a ball struck the femur point blank just between the condyles, it might merely leave a hole; if the same ball struck the middle of the bone, it might be shivered into fragments. If the wounding body be blunt or obtuse, and its velocity be less, the shock is not confined to the point struck, but is diffused over the whole bone or limb: for instance, if you place the hand at the extremity of a beam, and strike the other end with a very pointed hammer, the instrument penetrates the beam, but a very slight shock is felt by the hand; but if instead of the pointed hammer you use a broad one, the shock is often painful. In the one case, the violence is decomposed by the rupture of the ligneous fibres; in the second, those fibres resist and transmit the shock.

Indirect fractures, or, as they are termed by the French, by *contre-coup*, are frequent in large bones: if they be struck perpendicular to their axis, the fracture is direct; if they be struck according to their axis at one extremity, the other supported by another bone and resisting the shock is transmitted through their whole length, their extremities tend to approach, their natural curvature is increased, and if this proceed beyond a certain point, the osseous fibres are ruptured by *contre-coup*: thus, the femur, the tibia, and the humerus, are fractured by falling on the knee, the foot, or the elbow.

Occasionally, bones are fractured by muscular action; this is seen in the patella, the olecranon, and the calcis. This opinion is not universally admitted; many persons believe that the bone itself must have undergone some previous change. In the Archives, t. 13, p. 450, is a case where the use of nux vomica produced contraction so violent as to fracture the femur. Desportes mentions the case of a young negro, in whom during a violent spasmodic contraction, both femurs were fractured at the neck, and the bones protruded through the integuments. Chambers mentions the case of a lad whose arm was fractured in throwing a stone. Samuel Cooper has seen the arm of a muscular man fractured in missing a blow.

Symptoms.—Among the rational signs of fracture are the circumstances under which the injury has been received; (the grating which the patient alleges he has felt at the moment is very illusive:) pain, numbness, impossibility of moving the limb, must not be relied on alone. The pain may be the result of many circumstances other than fracture. Inability to move the limb may be a consequence of simple contusion. Numbness may result from the general shock or the partial concussion of the limb. Change of form, of length, of duration, inequalities when the bone is super-

ficially situated, crepitation and unnatural mobility, are the circumstances to which our attention must be principally directed. The deformity may not exist; it is the result of displacement, and there may be none. Crepitation, which the hand and sometimes the ear detect at the fractured point when the fragments are moved one on the other, may be easily ascertained when the bone is superficial, not always when the bone is deep, even with the assistance of the stethoscope, as suggested by Lisfranc. It is necessary to be on our guard so as to distinguish between the crepitation of bones, and that of certain sanguineous tumors—that of emphysema and certain conditions of tendinous sheaths. Unnatural mobility, shewn either by the spontaneous movements of the patient or by the examination of the surgeon. This mobility is easily seen where the part is composed of one bone, is not easily shewn in the forearm and leg when only one bone is fractured. Therefore, it results with regard to these signs, that taking either separately, it may be sufficient to indicate the existence of a fracture, although it may not have an absolute value.

Prognosis.—Our prognosis of fractures must vary with the bone implicated; the part of that bone, the kind of fracture, the age of the patient, his general condition. The smaller the bone and the deeper it is seated, the more difficult to maintain contact. A fracture implicating the middle of a long bone is usually less dangerous than one which affects their articulating extremities. When a bone is fractured at more than one point, it is very difficult to maintain the fragments reduced; and very frequently the consolidation is vicious, the limb remaining shortened and crooked. An oblique fracture is more serious than one which is transverse, because the fragments glide more easily one upon the other; an oblique fracture is not consequently so easily maintained when reduced, and the chance of shortening is therefore greater.

Fractures by *contre-coup* are less serious than those resulting from direct violence, the latter being always complicated by contusion. Fractures of the inferior extremity are, *ceteris paribus*, more serious than those of the arm; they usually require the patient to preserve the recumbent position. The most simple species of fracture is unquestionably that which occurs by indirect violence in a healthy individual; is transverse in its direction, occupies the middle third of a long bone, and at once admits of the employment of appropriate treatment. The most serious, putting out of the question complications, will be that in which the circumstances are the opposite to those above described.

LECTURES
ON THE
ALTERATIONS OF THE BLOOD.

BY M. ANDRAL.

Microscopic Researches on the Blood.

ON this subject a good deal of doubt still exists, as the facts discovered are frequently in opposition with each other. In 1673, Lewenhoeck described the blood as exhibiting a number of minute bodies, gifted with motion: he also described the shape and coverings of the globules. Boerhaave's system of *error loci* was based upon the relative proportions of the capillary vessels and globules. Huxham assigned great importance to these globules, and described, from his imagination, the changes that they are subject to. It has since been demonstrated by the microscope that the globules may be altered, as to their form, colour, volume, number, their affinities to each other, and their movements.

Form, which is lenticular in the mammifera, may undergo certain physiological and pathological changes. Their form becomes altered immediately the blood has escaped, and has ceased to circulate; and the same effect is produced by the contact of certain substances, such as the hydro-sulphuric acid. In birds, reptiles, and fishes, their form is elliptical; and some authors assert that sometimes globules of this form are to be met with in man; but, as in these cases the globules had been first dried and afterwards dissolved or diluted, I do not credit the assertion. Their form is changed when they circulate through tortuous vessels, as also when they pass through the very minute capillaries. So many alterations in their forms being thus produced physiologically, must render those which depend upon pathological causes very difficult to be ascertained. In cholera they appeared torn, their surfaces faded, and did not present the circular form. Their appearances in typhus fever are still a matter of doubt. Doctor Donn  says their form is altered in dropsy.

Colour.—Their colour in the healthy blood varies with the light by which they are seen, as it is a reflected or refracted one. Donn  describes globules of a white colour, and of a larger size than the red ones, as existing in the healthy blood, varying in number, but which were found most numerous in cases of dropsy. The red globules in the healthy condition do not always present the same shades of colour. Haller describes them as of paler colour in ill-fed animals; and Donn  says they are similarly changed in chlorosis, becoming pale and transparent.

Volume.—Their natural size is still uncertain (120th of a millim tre), the same globule being at one time larger, at another time smaller.

Number.—Is variable, but always considerable, and depends, in some measure, on the quality of the blood: they are more numerous in the arterial than the venous blood.

Age.—Denys asserts that, in the f etus, up to the third week after birth, the globules are found in the greatest number; that they diminish from this period to the fifth month, when they begin to augment to the fortieth year; and from this age to the seventieth year they again diminish.

Sex.—They are most numerous in man, whose blood contains 132 parts of globules out of 1000 parts, that of the woman containing only 92. In those of a sanguineous temperament, they are found more numerous, being in man in the proportion of 136 to 1000 of the blood, and in woman 126. In those of a lymphatic temperament, their number is diminished. Nourishment influences greatly the number of globules (Donn ); difference in diet diminishing their number from 132 to 87—They are more numerous in the carnivora than in the herbivora.

Average Proportions of the Globules in 1000 parts of Healthy Blood.

Average.		
Dumas and	129	{ 148 maxim. quantity.
Prevost		{ 115 minimum do.
Lecanu	132	{ 148 maximum do.
		{ 115 minimum do.
Denys	123	{ 173 maximum do.
		{ 164 minimum do.

In chlorosis Lecanu rates their quantity at 55 in 1000 parts. I have no reason for supposing that in inflammation their number is increased. In the commencement of scarlatina Lecanu has found in one case the number 144; in another 146. The same author has found, in organic diseases of the heart, the number diminish as follows:—101, 79, 51, 45, 43, 41, 40, shewing the proportion existing between the globules and the mass of the blood in eight cases of this affection. In diabetes their proportion was 132; and in typhus fever 115. In the healthy state, the globules are separated from each other; but in other cases they shew a tendency to coalesce together, so as not to be distinguishable: they move rapidly and regularly. In the normal state, there are vessels which do not carry the red globules, and an obstruction is produced if they by accident become engaged in them.

Alterations in the Composition of the Blood.

At present we do not know how the blood is formed. When I was studying

chemistry, the explanation that was given of its composition seemed quite clear and satisfactory to all the eminent men of that day; but now every thing belonging to it seems in a state of confusion; but we hope soon to see the uncertainty cleared up.

Alterations of the normal principles of the

Blood: First class.—First order. Organic matters—fibrine, albumen, colouring matter, fatty matter.

Second order.—Inorganic matters—gas, water of the blood, salts, iron.

In a second class we shall treat of those matters which are sometimes found in the blood, but do not enter into its healthy constitution; and in this class we shall find the matters of secretion, about which there is great discussion; we shall afterwards speak of the morbid productions, entozoa, tuberculous matter, &c. which are not found in the healthy fluid, and those substances which are not discovered by the aid of chemistry.

Berzelius states that the difference between the organic principles of the blood, viz., fibrine, albumen, and the colouring matter, is very difficult to detect; and he is of opinion that they may be varieties of one and the same principle or substance.

Alterations of the fibrine.—Its natural quantity is unknown, authors differing much on this subject. Dary says it increases in inflammation, and is found to be diminished in scurvy.

Its quantity is said to be altered in typhus. Magendie, by the abstraction of the fibrine from the blood, has induced consequences similar to those of typhus. In plethoria it has also been said to be augmented.

Alteration in its quality.—When it loses the faculty of spontaneous coagulation, the disease, which we have described under the name of dissolution of the blood, has been produced. The fibrine appears to constitute the organisable matter of the blood, and to form the false membranes when it separates from that fluid.

Alterations of the Albumen.—It has been asserted, but not proved, that like the fibrine, it is augmented in inflammation, and diminished in scurvy and typhus.

What is the state of the albumen of the blood in dropsy? Is it altered or augmented?

In certain forms of this disease, in which the urine contains albumen, its presence in it has been attributed to its being in excess in the blood. Another theory supposes the kidney to be diseased, and that it secretes the urine charged with it. In support of the first theory, it has been urged that if we inject serum into the blood of an animal, its urine will contain albumen; and also that in many cases it is found in the urine, the kidneys being sound. The result of my observations is, that in the

great majority of cases in which there is albuminous urine, the kidneys are also affected. The theory of Graves is, that the granulations which are found in the kidney are formed by the albumen which is stopped in the cortical substance of that organ; but I cannot yield to this opinion, for there are a great number of diseases of the kidney in which they are not granulated, and in which the urine is altered: my opinion is, that the kidney, like every other organ in a state of disease, is no longer capable of forming its secretions, or that it allows the blood to pass through it.

It often happens that Bright's disease begins with hæmaturia, which after a time ceases, the kidney preventing the blood from passing through, but allowing the albumen to do so; the office of the kidney permitting it to let pass a number of foreign principles, it may be supposed that when diseased, it will allow of the passage of the albumen. I think that this albuminous urine may be found whenever the kidney is greatly diseased, for I have seen it when this organ was in a state of atrophy or affected with hyperemia, tubercles, calculi, cancer, &c. The blood being impoverished by the diminution of its albumen, may be the cause of certain dropsies.

The albumen may become altered in its qualities, but such cases are hardly known. Berzelius mentions instances in which it has been changed into a fatty matter.

The red colouring matter of the blood may be augmented or diminished with the richness or poverty of the blood. Blue and yellowish colouring matters have been described as existing in the blood: certain principles of the bile are found in the blood in particular affections of the liver. Chevreuil insists upon the presence in the blood of a colouring matter, distinct from a red one; and he describes it as being of a yellow colour, and small in quantity, but capable of being increased. After severe accidents and great operations, the skin of the patient presents a yellow colour, not connected with the presence of bile; and the skin of persons bit by certain venomous serpents presents the same appearance. From their statements it would appear that there exists in the blood a colouring matter which becomes developed in certain pathological cases, and stains the skin yellow independent of the bile.

The yellow colour of the skin may be produced in three ways.

1. The bile, circulating with the blood, may cause it.

2. The development in the blood of an abnormal colouring principle, which has either been formed in it, or is merely an alteration of a yellow principle existing in the normal blood.

3. Extravasation of blood under the skin.

Alterations of the inorganic principles which enter into the natural composition of the blood.—These are water, alkali of the blood, iron, and salts. The blood contains a gas, which is the carbonic acid, and whose existence in the healthy blood is admitted by the greater number of chemists.

Alterations of the water of the blood.—What is the natural proportion of it? In a great number of diseases its quantity is much increased. The serum of the blood contains a prodigious quantity of water: according to Denys, 100 parts of blood contain 78 of water on the average. Bostock rates the proportion of water at 88; Berzelius at 90. Haller says, it varies from 73 to 93. In the batrachians, Berton found the proportion 90, and in the mammifera and birds 82 or 83.

When the water of the blood is increased in quantity, the clot formed is small, and the serum is abundant, as seen in anemia, in a high degree, and chlorosis. This condition may be named hydrohemia. Can we augment the quantity of water in the blood by modifying its composition, and by the injection of water into the stomach or veins? The blood disembarasses itself very speedily of the water which is placed in contact with it. When it does not contain its natural proportion of water, it may take some up to supply the deficiency; but when it possesses its natural quantity, it will not take into its circulation the water injected into the stomach. The experiments of injecting it into the veins have produced nervous affections, coma, convulsions, difficulty of respiration, suffocation, great discharges of water, watery effusions, the brain being found infiltrated, and the lungs oedematous, showing that the water which has been injected separates from the blood, and is thrown out of the torrent of the circulation, producing infiltrations and dropsies. These dropsies may disappear spontaneously by means of purging, copious sweatings, or abundant secretion of urine. After these sudden disparitions of dropsy, not preceded by sweating or secretion of urine, the brain becomes oppressed, coma and death taking place, or the patients may die with a panting respiration, followed by asphyxia, and in this last case the lungs are found oedematous. In these cases, the blood has taken into the circulation the fluid of the dropsy, and has thrown it on the brain or lungs. A case is related by Lecanu, of a man who, during forty days, made use of a large quantity of drink. The blood examined at the end of this period contained more water, the globules having much diminished; their proportion, at the beginning, being 154, and at the end of this time being but 111. This patient

was not restricted as to food, and neither the albumen nor the salts were altered. Great losses of blood very rapidly produce an increase in the quantity of water. A cat having been bled twice within the space of five minutes, the blood of the second operation contained more water than that of the first, and the same results have been obtained by the same means employed on man. Abstinence will cause the same increase, as will also chlorosis. In this latter affection, Lecanu found in 1000 parts of blood, 862 of water. This augmentation in the water may be acute or chronic. When a great proportion of water exists in the composition of the blood, it causes various functional disorders.

When the blood is in a state of liquefaction, serous effusions take place; when it is in a state of dissolution, and has lost the power of coagulating, hæmorrhages are produced; by abundant bleeding, we diminish the principles of the blood, thereby rendering it more liquid or fluid. We may bleed an adult very freely, without causing dropsy to take place, but it may be easily induced by large bleedings in children, as we see sometimes after loss of blood from leeches. Unwholesome food, a long time used, may bring on dropsy, such as a vegetable diet, or substances difficult to digest; and in this instance there are foreign particles introduced into the blood, which may produce its dissolution, and bring on scurvy. Can dropsy be produced by living in a humid atmosphere? Flocks of sheep, which have been exposed night and day to great humidity, are afflicted with dropsies and hydatids. I have seen persons who, on coming out of a bath, had a slight oedema of the legs, and a slight puffiness about the face; in these cases the transpiration through the skin had ceased, and the effusion into the subcutaneous cellular membrane had, in consequence, increased. In those countries where cold succeeds rapidly to heat—in regions placed beneath the equator, where a difference of twenty degrees of temperature is often felt between the heat of the day and the cold of the night—sudden dropsies are often produced between the evening and the following morning. In persons sleeping in those countries, on the damp earth, when the night is cold, the cutaneous perspiration ceases, this function is checked, the pulmonary perspiration diminishes, and the blood, in consequence of the suppression of these secretions containing more water, the serous and mucous membrane become vicarious to the suppressed functions. In this way we can also account for the rapid diminution of dropsies, which is sometimes effected by

an increased secretion from the skin and kidneys.

The quantity of water in the blood may diminish, and in these cases thirst is often severely felt.

Alterations of the inorganic principles which naturally exist in the blood.

Alkali is either free or combined with the albumen or carbonic acid. It is owing to the presence of soda that the blood is always alkaline. I have never found it acid, even in the cholera. Carbonic acid injected into the blood will give it an acid character.

Does the iron of the blood diminish in certain diseases? It has been supposed to do so in chlorosis, and the paleness which exists in this disease seems to sanction this suspicion. We are led also to this belief by induction, for there seems to be a relation between the colouring matter and the iron; and if in chlorosis we find the colouring matter diminished, it is a reason for supposing a corresponding diminution of the iron. Preparations containing iron improve the condition of the blood in chlorosis; but if the blood contain its normal proportion of iron, it will not receive any more from the exhibition of medicines containing this metal. Lecanu examined the blood of chlorotic persons; his examination tells us nothing. Dr. Fedish says it contains less iron; we do not place confidence in his analysis. We are therefore uninformed whether the blood in chlorosis contains less iron.

Salts of the Blood.—Stevens and Denys insist upon the importance of these substances. The salts and the chloruret of sodium hold in dissolution the albumen and the other principles of the blood, and if the chloride diminish, it will influence the condition of these principles. The addition of the chloride of soda liquefies the blood; the diminution of these salts ought to produce its coagulation, their increase dissolves it. These experiments have been made out of the body.

Alterations of the composition of the blood by the presence of matters which are not ordinarily found in it.

1. *Matter of the secretions.*—They do not exist in the normal state, but are found in the abnormal one. If an important secretion be suppressed, owing either to a disease of the secreting organ, or to its being taken away, the matters of such secretion are found in the blood.

2. They may be present in the blood, the excretory ducts being interrupted by some obstacle.

3. A secretion may be interrupted by

nervous influence, and its matters will be found in the blood.

4. On account of a superabundant secretion, uric acid, &c., are found in several tissues, without disease of the kidney existing, this organ being insufficient for separating this principle which exists in excess in the blood.

Fatty matter has been found by Christison in the blood in cases of acute articular rheumatism, and it has been said to exist also in it in cases of diabetes, and in disease of the liver. Tiedemann describes having found the salivary matter in the blood.

Matter of the Bile.—Some cases exist in which the colouring matter of the bile has been found in the blood. In jaundice, the blood is turned green by the addition of nitric acid, and the matters of the bile have been found in most of the solids and fluids. Is jaundice the only disease in which the blood has been found impregnated with the matter of the bile? In those affections which are called biliary, Martin Solon says he has found the bile in the blood; I have tried to find it in the variety of biliary pneumonia, but I have never succeeded in detecting the matter of the bile in the blood in any disease but icterus.

Matters of the Urine.—Uric acid has never been detected in the blood. The blood has never been found acid, and if it ever exists in it, it must be combined with a base. Urea has been detected in the blood. Dumas has removed the kidneys in living animals, and has found in their blood urea, which is the fundamental principle of urine, and which cannot be formed without its presence. Tying the ureters produces the same results. We shall now see what the cliniques teach us. When the kidneys were diseased, we have seen the blood passing through the filter of these organs, and mixing with the urine; at other times the albumen alone was allowed to pass through. What becomes of the urea in these cases? Sometimes the urine is found deficient in it, although albuminous; at other times it has been found in it. In some cases of albuminous urine the blood presented nothing particular; but in other cases I have detected alterations in its composition, as it contained a quantity of urea. Cases are related in which the solids contain urea; others, in which the urine has been met with in the principal secretions; I doubt them. Fisher mentions cases where it was secreted by a great number of organs. Is the presence of urea in the blood followed by any bad results? If the secretion has been slow, the accidents are not very evident; but if it has been caused rapidly, by taking away the kidney producing a suppression of urine, the results are

very evident. In cases where an acute inflammation has suppressed the secretion of urine, typhoid symptoms have followed, with all the symptoms of nervous re-action. Milk, or its principle, caseum, has been said to have been found in the blood; but these facts require confirmation, as chyle, albumen, or fatty matters, might have been mistaken for it. I do not know a well-authenticated instance in which its presence has been ascertained in the blood. In puerperal fevers, the caseum of the milk may perhaps be found in it.

The products of morbid secretions may be found in the blood.

Pus.—When this morbid production has been detected in the blood, we must inquire into its formation. It has either been formed in the blood itself, in consequence of this fluid having been converted into the pus, or it may have been secreted from the sides of the vessels in the situation in which it has been found. If thus secreted by the walls of the vessels, it may be found, distant from the spot where it was formed, as is sometimes seen in inflammation of the veins of the arm, whence it is carried with the blood into distant parts. Lastly, the pus may have passed into the blood by absorption.

In the following acute diseases, pus has been found in the blood:—in acute metritis, phlebitis (general or local), metropéritonitis, and once in acute articular rheumatism. In chronic disease it has been found in phthisis. In what part of the vascular system, excepting the lymphatics, has pus been found? It has been seen in the heart mixed with blood, and frequently in the veins, but I have never found it in the arteries, except in one case of circumscribed arteritis, produced by a partial inflammation. What are the pathological circumstances which accompany this purulent condition of the blood? They are numerous; sometimes large foyers of suppuration, or large suppurating surfaces; suppurating wounds and phlebitis; at other times there exist none of these circumstances, and we merely find an alteration of the blood, which is itself the source from whence the pus is produced. In other cases it is found disseminated and infiltrated through the blood, and closely intermixed with it. It may also be met with in drops, floating in the blood, but distinct from it, or forming small dépôts or abscesses, enclosed in a false membrane, which separates it from the clot of blood in which such a purulent deposit may be found enclosed. These drops of pus have been most frequently met with in the veins; whereas we more frequently find in the heart de-

posits of pus, imbedded in clots of blood but distinct from them.

Donné says, that pus, added to blood in a coagulated state, produces its liqúefaction. According to Maude, blood added to pus coagulates it. The same author, in beating up blood, perceived a membrane forming itself around the rod which he employed. If he added pus to the blood before he beat it up, this membrane did not form; however, if the quantity of pus added were small, the membrane appeared, but in a very indistinct form, and if the quantity of pus were increased there was none formed.

If we add pus to blood deprived of its fibrine, and examine it with the microscope, we perceive the coats of the globules becoming infiltrated, the globules themselves turning opaque, their forms lengthening, and, finally, they disappear.

From the fact of the globules of the blood differing from those of pus, it might be inferred that no difficulty would be found in distinguishing them from one another: such, however, is not the case. The globules of the blood vary in aspect, colour, &c. By the action of ammonia, pus becomes congealed; and on the addition of blood, the globules are dissolved. In some cases, however, certain portions of the blood become congealed by the ammonia; and this mode of experimenting is therefore inconclusive, and the *experimentum crucis* is yet to be discovered.

How does pus find its way into the blood? It must either be absorbed or secreted by the walls of the blood-vessels or of the heart, or formed by the blood itself.

The absorption of pus is a very rare case, and I do not think that its presence can be attributed to such an action; for if such were the case we should meet with it more frequently in cases of phthisis, for example; and even if it did thus find its way into the blood, it may undergo some alteration. I am, therefore, of opinion, that, in the majority of cases in which pus is found in the blood, it is not owing to absorption.

Pus is often found in the blood after phlebitis, but this disease will not explain all the cases in which it is so found. In some instances it has been detected where no traces of phlebitis existed.

In some cases, where pus is found in a vein, it mixes with, and is carried along with, the blood; but, in the great majority, clots are formed, which imprison the pus, and prevent it from circulating with that fluid.

Jessier mentions, that pus secreted in a vein can never enter into the torrent of the circulation, as it becomes isolated in

the place where it was formed. I am not so exclusive, for I have seen cases where this plug or clot was not formed, and where the pus was carried into the circulation. Gendrin is of opinion, that in certain cases the blood becomes altered, and is changed into pus. This theory comes from Dehaën. I am inclined to this view, which explains certain morbid phenomena.

Duplay relates a case in which the greater number of the blood-vessels contained no blood, but were filled with pus; the patient presenting all the symptoms of a purulent fever, unaccompanied with any signs of phlebitis.

To explain those cases in which we find abscesses or purulent deposits in different places, either in acute or chronic forms, we must suppose that the pus first became mixed with the blood, and afterwards separated, but by what process is uncertain. I think it probable that, in these cases, the blood itself is in fault, and that it forms the pus as it may form uræa, under different circumstances.

The theories to explain those purulent deposits are therefore uncertain, and they have been ably discussed by Dehaën.

Encephaloid matter in the Blood.

Has its presence been ascertained? The blood may present an alteration which may render it a very difficult question to distinguish it from the encephaloid matter.

In the cancerous diathesis we sometimes meet semi-coagulated blood, strongly resembling this encephaloid matter, plentifully deposited in the greater part of the solids and in many of the veins, and more especially in the vessels in the neighbourhood of the cancerous ulcer or deposit. It has been in particular in subjects who presented such encephaloid deposits in their solids, that this matter has been found in the blood, and which so closely resembles it; but I will not affirm that it is the encephaloid matter itself.

I do not know whether tuberculous matter has been detected in the blood.

An Italian has found, as he supposes, entozoa existing in the blood. It has been said that the presence of hydrosulphate of ammonia, calculi, &c. has been detected in the blood.

Principles in the Blood inappreciable by the help of chemistry or of our senses, but rendered evident by those organs becoming affected to which the blood is sent; this fluid presenting no visible alteration.

The blood of an animal exhausted by fatigue undergoes some alteration; for if

injected into another animal, it will produce death, accompanied with symptoms of poisoning. If the blood of an animal affected with anthrax (*maladie charbonneuse*) be injected into another animal, this latter will be infected with the same disease. We have, therefore, reason to suspect some alteration of this blood, although it will be impossible for us to detect it by any means with which we are acquainted. In the old writers, we often meet with the words "acrimony or sourness of the blood." These words may, perhaps, comprehend more than they seem to express. May they not refer to some alteration of the blood furnishing unhealthy elements or matters of secretion, which thus deteriorated would produce diseases in the solids? If we look for the origin of those general formations or deposits of uric acid which we find in the solids, we may find it in the blood which deposits in various parts of the solids, cartilages, bones, &c. By reflecting on these circumstances, and arguing from hypothesis, I think it more probable to refer to the blood those general morbid secretions, as tubercles, than to suppose an alteration of the solids in which we may find them. Do those furuncles which we see disappearing and returning after uncertain intervals, owe their origin to some alteration of the parts of the skin on which they are situated, or are they owing to some particular alteration of the blood? I am inclined to refer them to the latter cause, as we often find other secretions in a morbid condition producing discharges from the mucous surfaces, or disorders of the nervous system; and it is evident that these general symptoms depend upon some common cause. In a great number of diseases which have their origin in a common cause, we may ask if this cause is not to be found in the blood itself.

The blood may become altered by substances coming from without, and mixing with it. The kind of food may modify the blood, as well as different conditions of the atmosphere; many poisons which are capable of being absorbed by it—*miasmata*, virus, &c.

In the cases just alluded to, is the blood really altered, or does it merely carry along with it the elements of these substances?

In some of them it is not altered, and can disembarass itself of these poisons; in other instances it becomes really altered by the contact of these poisons, and the morbid condition produced is owing to the combined influence of the poison and of the alteration or morbid condition of the blood itself.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Treatise on the Causes and Consequences of Habitual Constipation.
By JOHN BURNE, M.D. Fellow of the Royal College of Physicians, Physician to the Westminster Hospital, &c. London, 1840. 8vo. pp. 257.

AFTER giving an account of the disposition, relations, organization, and functions of the large intestine, Dr. Burne relates more than sixty cases of disease which he supposes to have proceeded from constipation. Among them are cases of sick headache, pyrosis, gastralgia, menorrhagia, amenorrhœa, dysmenorrhœa, leucorrhœa, colic, dysentery, diarrhœa, diseases of the rectum, erysipelas, &c. &c. The following one may serve as an example.

CASE XXXII. — *Disease of the cardiac extremity of the stomach, and subacute-chronic inflammation of the cæcum and colon. Constipation.*

October 9, 1839.—Mrs.—, aged 21, married two years, has no child, menstruates regularly, though scantily and with pain. She complains of sickness and pain in the stomach after food, of whatever kind and whenever taken, which continue till the whole has been thrown up. Sometimes she vomits immediately the food has been swallowed, at other times not till the expiration of an hour. First the food is vomited, then a hot, sour, ropy fluid which burns the throat, excoriates the mouth, and sets her teeth on edge. She does not become easy till the whole of this fluid has come up. Her appetite is good, and she never feels satisfied; yet the moment she swallows anything the above symptoms are induced. She is weak, and much emaciated: the tongue is reddish, clean, moist: the pulse small: the hands and feet cold.

She has always suffered from constipated bowels: strong medicines being required to produce an action; and has now been a week without a dejection, notwithstanding she has taken aperients every other night. The stomach symptoms have existed three years.

On exploring the abdomen I find a tumor in the left hypochondrium, hard

and rounded, more perceptible in the erect than in the horizontal posture. It is situated deep, exactly in the region of the cardiac extremity of the stomach, being more forward and higher, and nearer the epigastric region, than the spleen. Connected with the gastric symptoms, I conclude it to arise from disease of the cardiac extremity of the stomach.

I find, also, tenderness and pain in the regions of the cæcum and sigmoid flexure, and along the whole tract of the colon, so distinct and well marked as to indicate a pathological condition of the whole of the large intestine: probably a subacute-chronic inflammation and thickening of the mucous and submucous tissues with contraction of the gut; states which are common consequences of the irritation of knotty, hard, scybulous fæces unduly retained in the large intestine. The aspect of the case is that of extensive disease both in the stomach and colon, advanced to a point probably beyond the power of medicine.

To take Hydrarg. Chloridii gr. $\frac{1}{2}$, Opii gr. $\frac{1}{4}$ after breakfast and dinner; Extract. Colocynth. Comp. gr. v., Opii gr. $\frac{1}{2}$ every night; and the Mist. Magnes. cum Magnes. Sulphat. et Decoct. Aloës Comp. every morning. To apply an Emplast. Hydrarg. cum Ammoniaco to the region of the stomach.

Oct. 16.—The medicines operate well upon the bowels. The mixture has been taken in the evening, it having been rejected by the stomach when taken in the morning. She has experienced no relief. At the end of October, when this report was concluded, no amendment had taken place. She suffered less in the horizontal than in the upright position.

Remarks.—This case illustrates the connection between organic disease of the stomach and habitual constipation, which latter preceded the stomach affection for years. The cardiac disease has occurred at an unusually early period of life. The pain and tenderness in the seat and course of the large intestine accord exactly with the symptoms and cases detailed by Mr. Annesley in his work on the Diseases of India; in which he has so amply shown that these symptoms indicate a morbid condition of the large intestine. The profession is much indebted to him for having pointed out and urged the necessity of exploring the

abdomen, and the certainty with which disease of the large intestine may be traced, even where there is no tumor to fix the attention" (p. 75).

In such a case as this would it not be worth while to try a brisk counter-irritation to the supposed seat of disease, (with tartar emetic ointment, for instance,) and the frequent use of warm baths?

After all, although in many or most of Dr. Burne's cases, constipation may have added to the disease, if it did not originally cause it, still it must be allowed that the use of purgatives is far from neglected in this country. We are inclined, indeed, to side with Dr. Holland, when he says, "If asked whether the use of purgative medicines, beneficial beyond all others under certain conditions, is not carried too far in modern English practice, I must affirm my belief that it is so; and each successive year of experience strengthens this conviction." (Med. Notes and Reflections, p. 98.)

We are, therefore, gratified that our author has dedicated a chapter to the causes of habitual constipation, and that in the next one there is a section on its treatment independently of medicine. Of all the causes of habitual constipation, he says, there is none so general as inattention to the calls of nature. "A misplaced sense of delicacy, an absolute disregard of the calls of nature, some engagement from which persons do not at the moment liberate themselves, the inconsiderate or ill-planned situation of the closet, or of the out-of-door cabinet d'aisance, all conspire to counteract the operations of nature and to originate constipation.

How often does it happen that ladies, feeling it not quite convenient to retire to the closet at the moment they experience an admonition, defer it till a more favourable opportunity; but this opportunity having arrived their efforts are powerless; the bowel will not then act; and disappointment and discomfort ensue. Delicacy on their part is carried to a most pernicious extent in England, while on the other side of the channel the reverse obtains; happily, perhaps, as regards health and ease. An English gentleman, while in France, having one day occasion to go to the cabinet d'aisance, found it occupied by a lady; the door not being bolted. Em-

barrassed, he retreated to his apartment; where in a few minutes, another lady of the family came to him, saying, "Monsieur! la place est libre!" The Englishman blushed for an instant, but, quickly recovering, said to himself, en allant, "Eh bien! If Madame feels no delicacy in this matter, why should I?" (p. 163.)

Dr. Burne has omitted to observe that the extreme reluctance to be suspected of visiting the Temple of Cloacina is *du plus mauvais ton*, and belongs to the pinched and frigid manners of the middle classes. Denman says, when speaking of retroversion of the uterus, a displacement caused by neglecting to make water, that "women who live in an humble situation of life, or in an unrefined state of society, are scarcely ever liable to this complaint, because they are free from the constraint of company; and those in the highest ranks of the most refined society, not being abashed to withdraw from company, are nearly in the same situation. But those who, in a middle state of life, with decent, yet not over refined manners, have not cast off the bashfulness of the former, nor acquired the freedom of the latter, are most subject to the retroversion of the uterus."—(Introduction to the Practice of Midwifery, 6th edit. p. 78.)

Something, no doubt, is sacrificed to decorum: but the immolation of health and comfort on its shrine is absurd and extravagant; and when it is generally understood that a Countess in her own right does not blush to leave the room, we may hope for equal boldness from an attorney's wife.

In well-constructed modern houses we believe it is a rule to have a water closet on at least two, if not three floors; nevertheless, there are too many dwellings to which the following observations are applicable.

"The want of proper conveniences is most severely felt by society at large, though now less unquestionably than formerly.

The situation of closets is often ill-judged. If of ready access, too exposed: if remote, inconvenient. In number too they are apt to be sadly deficient: one perhaps for a whole family, and this most unfortunately placed. Then, again, the out-of-door cabinet d'aisance is sometimes situated at a dis-

tance from the house, and the access to it often runs in front of the sitting room windows; the locality itself being often cold, damp, and repulsive.

One cannot help wondering to see so much pains bestowed on the arrangement and decoration of a house, while a disregard is manifested with respect to the closets and cabinets d'aisance, upon which conveniences, nevertheless, the health and comfort of a family and their visitors depend.

Is there any one who has not at times found the pleasures of a visit neutralized by difficulty in attending to the bowels? How often do both sexes suffer from unusual constipation when from home, especially while travelling abroad, for want of proper conveniences and opportunities; sufferings which mar all their anticipated enjoyments. Travellers on the Continent know well the miseries they have encountered in this respect. But we need not leave our own shores to experience annoyances like these; for in Britain itself there are towns in which a great part of the houses have not only insufficient conveniences, but absolutely none at all." (pp. 164, 165.)

Other causes of constipation are, the want of exercise, anxiety of mind, and sedentary habits and occupations. The poor girls who drudge for dress-makers and milliners sometimes work fourteen or fifteen hours a day:—"Many do not leave the house from Monday morning to Saturday night. So exhausted are they at the close of their daily labours, that I hear they can scarcely "drag themselves upstairs to bed;" the truth of which is too plainly told by the pale sallow faces, palpitating hearts, and swollen ankles which they exhibit." (p. 168.)

Then come pathological causes, such as deficiency of bile, diseases of the brain, stricture, organized bands stretching across the channel of the bowel, or a diverticulum. "A diverticulum is an anormal process from some portion of the intestinal canal, generally the jejunum or ileon, of from three to five inches in length, about the size of the middle finger, communicating openly with the bowel, but having its distal extremity closed, forming indeed a cul-de-sac, very similar to the appendix vermiformis, except that it is larger and has no mesentery." (p. 177.)

Or there may be a mechanical obstruction caused by swallowing foreign sub-

stances, such as magnesia, chalk, sulphur, cubeb, white mustard seed, pills, adulterated bread, fruit stones, or sesquioxide of iron (*ferri subcarb. Pharm.* Lond. 1824.)

In one case related by Mr. Brande, from four to six pounds of magnesia were found embedded in the head of the colon, though the examination occurred six months after any magnesia had been taken. The alum used to beautify London bread, though supposed by Dr. Paris to be only ten or fifteen grains in a quartern loaf, is justly considered by our author as a cause of habitual constipation. He relates a curious trick by which a baker was once brought to confess his toxicological practices:—

"The late Dr. Babington having often heard that the London bakers mixed alum in their bread—to which it was supposed to owe its whiteness—made several attempts to detect it, but without success. Being a man of humour, he determined to try another expedient. Having broken a loaf in two, he rubbed the surfaces with finely powdered alum, and directed that, when the baker next called, he should be informed. Accordingly the man was shown into the library, when the doctor, putting on a serious countenance, observed, 'I thought, Mr. Baker, you told me that you never put alum in your bread. Now,' producing the loaf, 'what is the meaning of this sparkling appearance, which any one may tell is alum by the taste?' Taken by surprise, and overwhelmed by so palpable a proof of the fact, the baker inadvertently replied, 'I don't well know how it can be, Sir, but suppose some accident has happened, for we don't in general put as much into the whole batch. And thus the doctor gained his point.' (p. 188.)

In the chapter on the treatment of habitual constipation, our author recommends early rising, the habit of frequenting the water closet regularly, exercise, and change of scene. We recollect that Locke, in his treatise on Education, wishes children to be *taught* to go to stool daily after breakfast.

Among articles of diet, our author recommends coarse brown or bran bread, figs, prunes, mustard seed, ripe fruits, and bacon. "A glass of cold water taken on rising in the morning, will in some promote an action of the bowels."

The remainder of the chapter is on the use of aperient medicines, and the

particular merits of several purgatives; of means applied to the large intestine; and of the treatment of obstruction of the bowels.

The last chapter is on the influence of constipation in causing the more prevalent diseases of India, and is abstracted from Mr. Annesley's great work.

Dr. Burne's treatise is the work of a sensible and industrious physician.

The Anatomist's Vade Mecum: a System of Human Anatomy. By W. J. ERASMUS WILSON. With upwards of 150 illustrations, by Bagg. London, 1840. Small 8vo. pp. 551.

MR. WILSON has done good service, both to the practitioner and the student of anatomy, by the publication of this compendium. He has given an excellent abstract of established anatomical knowledge, and has not neglected those late refinements, of which some are as yet struggling for existence. The following extract will not only give some notion of our author's manner, but will be new in substance to many of our readers.

The "*tensor tarsi* (Horner's* muscle) is a thin plane of muscular fibres, about three lines in breadth and six in length. It is best dissected by separating the eyelids from the eye, and turning them over the nose without disturbing the *tendo oculi*; then dissect away the small fold of mucous membrane, called *plica semilunaris*, and some loose cellular tissue under which the muscle is concealed. It arises from the orbital surface of the lachrymal bone, and passing across the lachrymal sacs, divides into two slips, which are inserted into the lachrymal ducts as far as the puncta.

Actions. * * * The *tensor tarsi*, or lachrymal muscle, draws the extremities of the lachrymal ducts inwards, so as to place the puncta in the best position for receiving the tears. It serves also to keep the lids in relation with the surface of the eye, and compresses the lachrymal sac. Dr. Horner is acquainted with two persons who have the voluntary power of drawing the lids inwards by these muscles, so as to bury the puncta in the angle of the eye." (p. 136.7.)

The wood-cuts do Mr. Bagg great

credit. Among those which particularly struck us, are fig. 4, giving a lateral view of a dorsal vertebra; fig. 24, representing the external or basilar surface of the base of the skull; and fig. 90, where the superficial muscles of the posterior aspect of the leg stand out in bold relief. If we might hint a fault, we would suggest that the frontispiece and the engraving on the title-page are not in good taste, and remind one of Holland rather than Greece.

The type is small, but exquisitely distinct.

CASE OF
SPONTANEOUS DISLOCATION
ON THE
DORSUM OF THE ILIUM.

To the Editor of the Medical Gazette.

SIR,

You will greatly oblige me by inserting the following case in your valuable periodical, since it forcibly demonstrates the error of not immediately and actively attending to what are too often considered trivial accidents.—I am, sir,

Your obedient servant,

C. M. DURRANT, M.D.

Ipswich, April 24, 1840.

A gentleman, passed middle age, residing in the country: while walking in his plantation, on turning suddenly round, his foot slipped, and he fell to the ground, his right hip forcibly coming in contact with the projecting stump of a tree. Great pain and syncope were induced, but on the following morning the pain of hip was so much alleviated by rest, that the patient rose and pursued his usually active avocations. The pain of hip, however, remained, and was much aggravated by riding on horseback, especially on mounting. Some months after the accident, he was attacked with spasmodic stricture of the urethra, attended with a considerable discharge of mucus from that canal, and which was rendered very profuse by the constant use of the catheter; this, together with the stricture, for a long period combated the most judicious treatment. The pain in the neighbourhood of the hip continuing, it was believed both by the gentleman and his friends to be neuralgic, and treated as such, but without relief. A belladonna plaster was ordered

* "W. E. Horner, M.D. Professor of Anatomy in the University of Pennsylvania. The notice of this discovery is contained in a work published in Philadelphia in 1827, entitled 'Lessons in Practical Anatomy.'"

to be applied to the hip, but by mistake a blister was substituted, which, by producing excessive local and general irritation, aggravated very considerably the existing symptoms.

Up to this time, the patient (who now went to London for advice) was not confined to the house, but took daily exercise on foot. He was totally unable to pass his water without the catheter, but by the constant use of this instrument, (which was finally retained in the bladder for ten days without removal) by opiates, and other means to allay constitutional irritability, the stricture was at length cured. During the treatment of the stricture, but before the cure was complete, the pain of hip increased, amounting, on the slightest motion, to excruciating agony. The pain the patient suffered at this stage of the disease is beyond description; this, combined with total absence of sleep, colliquative diarrhœa, and profuse night perspirations, baffling all the remedies prescribed to check them, appeared too evidently hastening the case to a fatal termination. Notwithstanding the above distressing symptoms, perfect rest, the continued use of powerful anodynes, and above all, as early as could be attempted, removal from London, to the accustomed country air, effected by short stages, and the use of a water couch, aided by a most excellent constitution, at length produced a beneficial change; the patient, after suffering one or two relapses, gradually recovered, but not till spontaneous dislocation had supervened.

The limb is now shortened to the extent of from three to four inches, with the other symptoms of perfect dislocation on the dorsum of the ilium. The patient, at first unable to lie on the affected side, can now do so with ease; he cannot yet, however, bear much pressure on the limb. The general health is good; stomach slightly irritable, but easily regulated by mild aperients. There is no remaining symptom of stricture, and the patient is enabled, with the assistance of an arm and one crutch, to take prolonged daily exercise. There is also an ultimate probability of deriving assistance from a raised or patten shoe.

REMARKS.—The above case appears one of peculiar interest in many points of view.

The inflammation of a chronic character which in the first instance attacked the tissues of the hip-joint, much aggra-

vated by constant exercise, produced such irritability in a naturally excitable constitution, as to cause subsequently spasmodic stricture of the urethra. Until this period no professional advice was sought.

Prior to the cure of the stricture, we observe the inflammation assume an active character; the ligaments and synovial membrane quickly run through the degenerative process, spontaneous dislocation takes place on the dorsum of the ilium, where nature, assisted by a good constitution, is doubtless adapting the misplaced limb by the formation of an artificial joint.

The above is one of the many cases which are frequently allowed to pass as too trivial for surgical interference: the error is commonly discovered when too late, the period of prevention or cure being irretrievably passed. This is particularly illustrated in the case under consideration, for had active measures been adopted at the time of the accident, by local bloodletting, fomentations, purgatives, &c., combined with absolute rest, the above distressing sequel would, in all probability, have been prevented.

ON THE
INDICATIONS TO BE FULFILLED
IN
DIABETES MELLITUS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the accompanying paper be deemed worthy of publication, you will oblige me by giving it a place in your journal.—I am, sir,

Your obedient servant,

CHAS. MAITLAND, M.D.

St. George's Hospital,
May 4, 1840.

The efforts of physicians in treating cases of diabetes mellitus appear to be still as much directed to the kidneys as they were five years ago; yet, since that time, sufficient facts have been accumulated to render it more than probable that these organs are nearly unconcerned in producing the mischief usually attributed to them.

In deference to the opinion of the profession, I have said, "more than probable;" but if the following argu-

ments are legitimate, and cannot be opposed by others of equal force, it is high time to change the plan of attack, and not to waste our energies upon those organs which appear to be engaged in the relief of the oppressed system.

By a reference to McGregor's "Essay on Diabetes," and my "Experimental Essay on the Physiology of the Blood," the following facts may be collected, which, I believe, have not been disputed by subsequent inquirers.

The stomach, in diabetes, has the property of forming sugar, from animal as well as from vegetable food.

Sugar is contained in the blood, urine, saliva, and stools of diabetic patients.

Such patients pass more urea than healthy ones.

No urea has been found in their blood, though albumen has been found in their urine.—(Bouillaud, Clinique Med. III. 289.)

Let us now look at the morbid anatomy of the question. Andral says, (Treatise on Pathology), "Of all the lesions presented by the kidneys of those diabetic patients whom I have examined, hypertrophy is the most common." Again (Path. Anat.), he alludes to "the state of paleness and anemia which has long been regarded as their principal alteration," and adds, "of all the post-mortem inspections published during the last ten years, there is none, that I know of, that has presented the anemic appearance of the kidneys, so much spoken of." The observations of others, including those which were made with the microscope, seem equally to prove that no perceptible morbid alteration is yet found regularly accompanying fatal diabetes.

A strong argument may be deduced from a comparison between this disease and renal dropsy. In the latter, the organic disease of the kidney has been fully established, and the results (as far as chemical pathology is concerned) are as follows:—

In the healthy state, the blood contains (besides numerous other constituents) water, albumen, and urea: the kidney is charged with the office of removing *part* of the water, *all* the urea, and *none* of the albumen. A most arduous commission, perhaps requiring a greater supply of vital energy for its performance than is bestowed on any

other secreting organ: for the kidney furnishes the largest of the secretions; it preserves the whole of the fluid passed through its ducts from any admixture of albumen, and it drains off the urea from the blood with such accuracy that it has not yet been detected in that fluid in health. We must not forget, in addition, that urea is found (by chemical tests) in *no part* of the healthy system *but* in the urine; and that albumen exists in *every part* of it, solid or fluid, *excepting* the urine; which fluid is strictly excrementitious, and therefore not required to contain an element so universally applicable to nutrition as albumen appears to be.—(Experimental Essay, p. 84.)

But when the granular degeneration is established, the kidney, like a sentinel negligent or physically incompetent, suffers to pass some of the albumen that should have been rejected, and leaves in the blood some of that urea that should have been carefully extracted; but no new matter is elaborated from the blood, and no function performed analogous to what has been attributed to the diabetic kidney. Then we find, during the prevalence of renal dropsy,

In the Blood.	In the Urine.
Defect of albumen.	Excess of albumen.
Excess of urea.	Defect of urea.
" water.	" water.

But in diabetes mellitus,

In the Blood.	In the Urine.
Excess of sugar.	Excess of sugar.
Excess of water.	Excess of water.
Urea unknown.	Excess of urea.

I think these facts point distinctly to the conclusion, that in the case of renal dropsy, the kidney *deranges* the constitution of the blood, by imperfect performance of its function; while in diabetes, the secretion is *deranged* by the organ being compelled to remove from the blood, elements, exceeding in quantity and number those which fall under its change in health. No wonder that Andral finds hypertrophy in the diabetic kidney, any more than that the same alteration is found in the obstructed heart.

Perhaps no disease has more exercised the ingenuity of reasoning physicians, or furnished a more fruitful theme for false reasoning, incorrect and unfounded data, than the present. The cases in

which diabetes occurs are by no means very rare, and each one stimulates the medical attendant to renewed efforts to make some progress in understanding it. Yet, little has hitherto been done; perhaps because we seek too remotely for what we miss; and it is notoriously easier "to ascend the bright heaven of invention," than to tread patiently the humble path of observation and close induction.

The following suggestions are offered with diffidence, and in the hope of seeing the subject more ably treated by others.

May not diabetes mellitus be considered as a complication of two distinct lesions in the system—one, a saccharine diathesis, analogous to the excess of nitrogen in the uric acid diathesis, produced by a tendency of the aliments to degenerate into sugar, after the manner of starch and hordein; and the other, an irritation in the stomach and kidneys, leading to excess of fluid swallowed and excreted?

Three cases of diabetes insipidus examined by Macgregor and myself, gave 310, 336, and 400 gr. of urea *per diem*, respectively, the usual amount of healthy urea being 360 gr. daily. These cases shewed a total absence of sugar; therefore they establish the fact, that there may be abundant flow of urine (in one case, 26lbs daily,) simply diluted.

May not the sugar be a source of irritation; first, to the stomach, causing thirst, and secondly, to the kidneys, causing diuresis? In support of the last opinion, may be mentioned the facts, that sugar is an irritant applied externally; that it causes thirst when taken in excess; and that in the only case of diabetic blood which I have analyzed, the water was in excess, in the proportion of 815 to 783.

The degeneration of aliments into sugar cannot be ascribed to a deficiency of the nervous influence presiding over the stomach, but to its morbid direction; for sugar is formed by the diabetic stomach from animal materials, which can be made to yield it under no other circumstances.

Lastly, are the means usually employed to correct the saccharine tendency, such as can be reasonably expected to benefit the supposed irritation of the stomach and kidneys?

THE HORLEY GREEN CHALYBEATE.

To the Editor of the Medical Gazette.

SIR,

I BEG to announce to the profession, through the medium of your periodical, the restoration of the Horley Green Mineral Water, once so celebrated for its medicinal efficacy, and the results of its new analysis, by Mr. West, of Leeds.

In the year 1790, Dr. Garnett published, what was considered at that period, a very valuable treatise on the subject, embracing an elaborate analysis, to which a series of successfully treated cases by this water was subjoined; since which time, however, from one cause or other, to which I need not refer, the spring has been gradually permitted to fall into comparative desuetude and neglect, until at length, more recently, it had become entirely lost—numbers of people, notwithstanding, visiting the place annually on the three first Sundays in the month of May, in a vain search for this fountain of Hygeia. On a visit of Dr. Granville to this neighbourhood, we were unable to discover more than the site of the well, which was enveloped by the ruins of the Spa-house that originally enclosed it. On removing these remains, a slender stream was found flowing into its receptacle, which, when tested with the tincture of galls, and an aqueous solution of ferrocyanide of potassium, afforded no indication of the presence of iron, and must, therefore, have consisted of top waters infiltrating the shaly soil around, without any admixture of the chalybeate. Sundry explorations in the vicinity, which need not be detailed, ultimately led to the discovery of the water in question, to which I now invite the attention of your readers, as examined by Mr. West.

The Horley Green Water contains per imperial Gallon,

Carbonic Acid Gas,	5.5 cubic inches.
Nitrogen,	7.25 do.
grs.	
40.77 Sulphate of iron (dry, or 74.5 in cryst.)	
15.26 Sulphate of Lime (or, 19.3 in cryst.)	
5. Sulphate of Magnesia (or, 10.25 in cryst.)	
.32 Chloride of Sodium (or, .59 in cryst.)	
.93 Silica.	
1.22 Alumina.	

63.5 Total solid matter.

These results differ widely from Dr. Garnett's, but my present object is not to account for the change which all the mineral springs in the course of years undergo, and which is remarkably instanced in the analysis of Professor Phillips, of the Scarborough waters, as compared with that of my own and all previous hydro-analysts, but simply to lay before the profession and public generally the chemical nature of the Horley Green Spring, leaving its therapeutical agency to be inferred, or drawn from the forthcoming work of Dr. Granville, on the Spas of England.

The decomposition, from the action of the atmosphere, which the artificial preparations of iron undergo, becoming inert sesquioxides, as in Griffith's mixture, and the common carbonate, &c., it will be an important desideratum in medical practice to possess a spring from which, by the addition of four or five grains of carbonate of soda to a tumbler glass full, we can at once obtain the like quantity of the carbonate of the metal in its pure and active state, as well as the proto-sulphate at the source. That by exposure the latter soon becomes the persulphate, I am aware, and more rapidly so, when in solution than in crystal.

The Spa is situated a mile and a quarter distant north-east of Halifax, on the west ridge of the romantic valley of Shilden-dale, and an erection is in progress by the proprietor, commensurate with the importance of the acquisition.

I have the honour to be, sir,

Your obedient servant,

W. ALEXANDER, M.D.

Physician to the Halifax Infirmary,
and General Dispensary.

Halifax, May 5th, 1840.

publicum sit, dicendi periculum non recuso."

CICERO.

PRELIMINARY EXAMINATION.

THE great and hitherto insuperable evil in the plans of medical education and examination is, that those students whose

consciences do not vividly picture to themselves the horrors of incompetent practice, can obtain, in six weeks, a quantity and kind of knowledge, which will enable them to pass, and which they conceive will carry them with credit through their professional career, while in reality it will remain with them no longer than it has taken them to attain it. We believe that the system of imparting this temporary knowledge to those among medical students who are inclined or compelled to resort to it, is now practised in a style very nearly approaching to perfection; and were its object more honourable, or its effects less mischievous, the highest credit would be merited by those professors of the art who have of late years so improved it, so that with no more diligence than the fear of rejection will supply, the student of the least intellectual capacity, and with the least previous professional acquirements, may deem a creditable and speedy passage through his examinations a matter of certainty. When, however, it is considered what a real scourge an incompetent practitioner is to all who may fall into his hands, and that in too many cases other qualities which he may possess may serve to cover his professional defects, and even make him peculiarly acceptable to the near-sighted public, few questions relating to medical education can be more important than to determine how these illicit modes of acquiring useless knowledge might be prevented; so that by cutting off all hope of a diploma from the undeserving, the idle student might be made industrious, and the industrious might receive the reward which he so fully merits, but now so rarely obtains.

The system of *cramming*, which among the junior members of our profession has acquired the figurative but very expressive name of *grinding*, (probably from its giving more edge than

substance to the knowledge,) is adopted in various degrees by the candidates for every kind of diploma. For all, we believe, the system pursued is the same; differing from each only in the expense, which is usually directly proportionate to the price and presumed respectability of the diploma. And this fact clearly shows, that no system of examination at present adopted is capable of entirely preventing the evil practice; for few modes of trial have ever been suggested of which examples are not to be found in some of the diplomatizing bodies in this country; and if we go on to France, where the examinations have certainly had every pains bestowed upon them, the same illicit mode of study is as nearly universal, as in this country it is among the candidates for the license of the Society of Apothecaries.

But although there may be at present no mode of examination capable of perfectly counteracting the practice of obtaining only that superficial and temporary knowledge which may just enable its possessor to pass, still it is far from true that the mode of examination has no influence on the frequency with which the practice is adopted.

Taking only the candidates for the College of Surgeons and the Apothecaries' Company, (of whom our knowledge permits us to speak with some certainty,) the number of those who are *ground* for the examination at the latter is nearly four times as great as of those who undergo the same process of preparation for the former; and we believe we do not at all over-rate the proportion, when we say, that four-fifths of the students in London are thus rendered capable of passing their examination at the Hall, without the least warrant that they possess any knowledge which they will not lose in the first six months after their fitness for practice has been certified by their examiners. Of course, we are far from believing that so large a proportion

are unfit for their professional duties; on the contrary, we know that many students resort to this unfair mode of preparation most unwillingly, and with deep regret. They are compelled to it, by the belief, (and we fear it is a well-founded one,) that the examination, to which they will be subjected, is not such a one as will test their real and profitable knowledge of medical practice, but one composed of the most heterogeneous questions, many of which have only a very distant relation to medical practice, and all of which require certain fixed and conventional answers, which are not to be learnt by a diligent attention to the several subjects taught in the schools, and to which the only key is the book of "Hall Questions and Answers," kept by each private tutor. The common practice, therefore, now is, for the more industrious class of students to learn their profession without any reference to their examination at this institution, and then, neglecting for a time their professional studies, to learn, by the royal road of grinding, the quirks and technicalities which can alone secure them their license. The less industrious, on the other hand, do not learn their profession at all; but they also, by a somewhat more extended course of peculiar and private instruction, render their success equally secure; and it is matter of common belief, and, to our own knowledge, it has often distinctly appeared, that more credit has been bestowed by the examiners on this latter than on the former class. In fact, although it forms no part of the plan or intention of the private tutors to impart any knowledge which may be useful in practice, yet it is notorious that a considerable proportion of the pupils of some of the more skilful of this class of instructors receive what are called the honours of the Court; that is, are complimented by the examiners on the large amount of their knowledge, and their peculiar fitness for medical practice.

But really these, and other similar errors in the system of examinations at the Apothecaries' Hall, have been so often pointed out, and the Board, in their attempts to correct them, by rendering the examinations more difficult, have so invariably adopted the course which has rendered private tuition at once more necessary and more successful, that we almost despair of seeing any improvement, and are forced to fear that, while the Hall stands, *grinding* must flourish.

For all the other boards of examiners the practice is far less frequently resorted to; not because the examinations fix a lower standard of actual medical knowledge, but because their character is more straight-forward, and the knowledge they require is that which a student may legitimately obtain by a fair degree of attention to the several studies of the schools, and to the practice of his hospital. The scope of these examinations is much more limited as to the number and diversity of their subjects; but in each subject into which they do enter, as high a standard is fixed as it seems fair to require a candidate to attain; and, with moderate industry, it may be attained by all. Illicit assistance is, therefore, sought for only by the positively idle, or the very timid; and it is much to be lamented, that while, of late years, such great exertions have been made by every board of examiners to improve their system and raise the amount of their demands, no scheme has been devised by which the incursions of the former class can constantly be prevented. The improved examinations, and the almost absolute impossibility which now exists of knowing beforehand more than a small portion of the questions that, as it is said, "are sure to be asked," by curtailing the number of stock-subjects, have undoubtedly effected much good; and still more has been done by every addition to the practical and manual part of the examination, which we hope to see constituting each

succeeding year a larger proportion of the whole. But still the system is far from perfect, and many undeserving candidates break through its fences.

It is probable that no single means will ever be sufficient entirely to put a stop to the practice which we have reprobated; but we feel sure that one which would tend much to lessen its frequency, and to counteract its mischief, is the system of previous examinations, which, from a knowledge of their good effects in our universities, we recommended a long time ago, and which the London University has since adopted into its scheme. The return of the season for competitions among the pupils of the several schools has induced us again to revert to this subject, and to urge that these examinations should be made use of in improving the general scheme of medical education. As they are at present conducted, they do not always effect even the limited good which is their object; for, not being compulsory, they are engaged in by only a small proportion of the pupils; and it often happens that the timid lose the reputation they might gain, through fear lest they should have the disgrace of being beaten, while those who are possessed of sufficient assurance save their credit by avoiding the chance of a defeat. The result is that, taking all the schools together, not more than one-fifth of the pupils engage in any of the examinations; and the honour of success is decreased, while, in a corresponding proportion, the disgrace of failure is augmented.

But the benefit of these school-examinations ought not to be limited to the excitement of an increased industry in a small proportion of the students: they should be made compulsory upon all; and the having engaged in one or more of them should be made an essential condition for admission to the ultimate examination for the diploma. For the examinations themselves, the immediate

benefit would be that the stimulus to unusual industry would be universally applied, for there are few who, when they are forced into a contest, will not do their best to gain honour in it; and that while the merit of success would be enhanced by the greater difficulty of excellence over a greater number of opponents, the demerit of failure would be diminished by the increased number of those who shared in it. And for the general scheme of education, the advantages would be scarcely less. To the industrious, a repetition of examinations would be by no means irksome—not so irksome as the constant and perpetually changing schemes of registration which are now continually being inflicted upon them; and, to the idle, for whom alone these regulations and restrictions are necessary, it would insure that the whole period that is intended for education should not be lost, as it is now, in the assurance that a few months' *grinding* are enough to pass, but that a more constant course of study should be absolutely necessary. At least, if the number of examinations to be passed were increased—if, for example, one were instituted in each year of study, each pupil would have to prepare himself three times instead of once, and there would be a three-fold instead of a single chance that he might retain some of the knowledge thus acquired. But with this plan, the examinations, being at least in part conducted by the teachers themselves, would of necessity assume a higher and a more straightforward character; and if the system of private tuition continued, as it probably would, its method must, in a corresponding degree, be changed, and, instead of providing a few weeks' store of useless and evaporating knowledge, which is all that it can now pretend to, it might be made to supply sound and profitable knowledge to the pupil.

ACCOUNT OF LAURA BRIDGMAN,
AN AMERICAN GIRL, WITH ONLY ONE
SENSE.

BY DR. JULIUS, OF HAMBURG.

DURING the last half century, several cases have been published of deaf and dumb persons who were also blind. The first instance described within this period is that of James Mitchell, who was accurately observed by Dugald Stewart; the last is Julia Brace, an American, in the Deaf and Dumb Asylum at Hartford, in Connecticut, whom I have seen. She was twenty-six years old, rather dull of sense, and ignorant, but with an acute power of smell.

There is now, in America, a girl even less endowed by Providence, of whom I will proceed to give an account, partly from the sixth and seventh reports of the Boston institution for the blind, and partly from a letter written to me by Dr. S. G. Howe, the director of the institution.

Laura Bridgman, a very pretty girl, lively, and full of spirits, was received into the asylum just mentioned in 1837; she had been blind, deaf, dumb, almost without smell, and, therefore, with a very blunted taste from early childhood. She cannot smell roses or eau de Cologne, though brought close to her, but sharp and pungent vapours seem to affect her olfactory nerves. She was born at Hanover, in New Hampshire, of respectable and intelligent parents, and suffered, while yet an infant, from very painful and dangerous fits, the nature of which does not seem to have been properly understood. Up to the age of twenty months, though pretty and attractive, she remained very feeble, so that a breath might have blown out the flame of life. At this period, however, she began to be stronger, and her intellect quickly developed itself, so that at two years old she was more clever and lively than other children of the same age: she could speak several words, and distinguish A and B. After the lapse of a month, however, she was seriously ill, and, indeed, almost dying, when the disease abated and threw itself entirely on the external organs of the senses; for, at the end of five weeks, it was discovered that sight and hearing were destroyed for ever. She passed seven weeks in pain and fever, during which time she ate absolutely nothing. For five months she was obliged to remain in a darkened chamber, and a year passed away before she could walk without support, and two years before she could bear the unmitigated light of day. Her health and strength continuing to increase, she was able, when four years old, to walk about

the house, and showed (though not by looks or words, as she was blind and dumb,) the wish to be employed. At first she was able to speak the few words she had previously learned, but, as she no longer heard her own voice, she gradually lost the power of speech entirely; the last word she was heard to pronounce distinctly was *book*.

In addition to her deafness, dumbness, and blindness, her exclusion from the external world was so entire, that she was almost destitute of smell, and could only smell the most pungent things; this destroyed one-half of the faculty of taste, and her indifference in this point became manifest. Yet this night of the senses did not extend to her mind. Every day she became more active and more cheerful, and, retaining the sense of feeling, took the greatest delight in learning a new stitch, a new way of knitting or embroidering, a new word, or finding out the method of using some new thing; and she shewed the quickest comprehension for these methods of enlarging her knowledge.

Three years afterwards, Laura, who was then eight years old, entered the institution for the blind. There she is continually in motion, runs about the house, up and down stairs, plays with her toys, and is happy with the other children. She can dress and undress herself quickly and regularly, and behaves at table, and everywhere else, indeed, with perfect propriety. She knows each person in the house by the touch, and has a great liking for them. She has learned to sew, knit, and embroider, and is as industrious and clever in these matters as the other children. Moreover, she has a lively sense of propriety, is cleanly, tries to deserve praise, likes to be neatly and prettily dressed, and makes others remark it. She has so strong a propensity for imitation, that she will sit down, and hold a book before her face, because she has perceived that those who read do so. It is difficult to say whether her sense of right and wrong depends on the one being praised and the other blamed by those around her; but it is certain that she retains nothing that belongs to any one else; and if she finds a bit of apple or cake, she does not eat it till she has been told by signs that she may. It evidently gratifies her to banter other persons, or make them wonder. The alternation of her feelings can be clearly perceived on her countenance, where hope and fear, pleasure and pain, self-approbation and repentance, are reflected in turn; and when she endeavours to get to the bottom of a thing, her face puts on the expression of reflection and strained attention.

When Laura was admitted into the institution, it seemed doubtful whether it

would be possible to teach her any regular system of signs by which she might express her thoughts, and understand those of others; but it was thought highly desirable to make the attempt, which has succeeded in part. At first, common objects were taken, such as a knife, spoon, or book, with their names fastened to them in letters in relief. She was then made carefully to touch the object, together with the name appended to it; and then another piece of paper was given her to touch, on which the name was printed in relief, which she quickly learned to connect with the object. Afterwards the name of the object in relief was put into her hand, and she had to find out the object among a number of things spread before her. Suppose the word *key* had been given her, and she could not find one on the table, she would get up, grope her way to the door, and, with the expression of marked satisfaction, she would hold the paper against the key in the door.

In these exercises, no reference had been made to the composition of words out of letters; but to try the accuracy of her knowledge, the next step was to put metal letters in her hands, which she soon learned to arrange, and thus spell the required word. When the teacher, for instance, touched the child's ear, or placed her hand first on a book, and then on the letters, she immediately began to seek for the letters singly, and arrange them in a little frame prepared for this purpose. When the word was properly set up in this way, she showed her satisfaction, and assured her teacher that she understood the word, by touching her ear, or the book, with the letters that composed it.

The next step consisted in teaching the child the order of the letters in the alphabet, after which she was taught the finger alphabet of the deaf and dumb. When she had been four months in the institution, it was wonderful and delightful to see with what zeal, accuracy, and quickness, she went on in her work, and in augmenting her small stock of words. When the teacher gives her a new object, for example, a lead pencil, he first lets her examine it, and obtain an idea of its use, and then teaches her to spell its name, by forming the letters of it with her fingers. She then takes hold of her hand, feels the fingers as the different letters are formed, turns her head somewhat on one side, like an attentive listener; her lips are open, and she scarcely breathes, until her countenance, which is at first anxious, gradually puts on a smile, as she comprehends the problem. When this is over, she lifts up her fingers, and spells the word according to the finger-alphabet; then takes the metal characters, and sets up the let-

ters singly; and lastly, as if to assure herself that she has done all right, takes the letters of the word collectively, and brings them into contact with the lead pencil.

A year later, Laura had already attained great skill in spelling according to the alphabet of the deaf and dumb, in which she spells words and sentences, which she knows so quickly, that only those who are accustomed to this mode of speaking can follow with their eyes the rapid movements of her fingers. But wonderful as is the rapidity with which she writes her words in the air, still more surprising is the ease and correctness with which she reads words written in the same way by another person. She does it by taking hold of his hand with her's, and follows each movement of his fingers, imprinting upon her mind one letter after another, as he expresses it. Thus she entertained herself with her blind play-fellows, and nothing more clearly shows the power of mind in subduing matter than her meetings with them. For if much talent and cleverness are requisite for two persons who speak by gestures to expound their thoughts and feelings by their features and by the motion of their body, how much greater is this difficulty when both persons are shrouded in darkness, and one of them cannot even hear?

When Laura goes through a passage in the house, with her hands stretched out before her, she instantly recognizes each person that she meets, and goes up to him with a sign of recognition; but if it should be a girl of her own age, particularly one whom she loves, a brilliant smile of recognition immediately appears; she embraces her arms, takes hold of her hands, and begins that rapid conversation with the fingers, whose motions conduct thoughts and feelings from the outer works of one mind to those of the other. Then follow questions and answers, an exchange of joy and sorrow, kisses and adieus, just as with young children in the enjoyment of all their senses. What a lesson for those philosophers who attribute the superiority of man merely to the possession of his external senses, and will allow him to be no more than the most perfect of animals!

Nevertheless, it must not be supposed that she knows as much as other children of the same age: at nine years old her knowledge of language was not greater than that of an ordinary child of three. As to mind and morals, however, her feelings and inclinations, her sense of propriety, of justice, of property, and so on, are as developed in her as in other children.

Laura is perfectly able to understand short sentences expressing actions, such as "shut the door," "give me a book," or

as she expresses it, "shut door," "give book;" for she understands the meaning of "the" as little as a child just beginning to speak, who puts in "the" and "me" only from imitation. When she is left alone, she seems quite happy with knitting and sewing, and can occupy herself for hours. If she has nothing to do, she entertains herself apparently with imaginary dialogues, or the freshening of past impressions. She counts with her fingers, or spells the names of things lately learned, according to the finger-alphabet of the deaf and dumb. In these solitary dialogues with herself, she reflects and draws conclusions. If she spells a word wrongly with the fingers of her right hand, she immediately strikes it with the left, as a token of disapprobation, as her teacher is accustomed to do; but if she spells it rightly, she strokes her hand and looks pleased. Sometimes she spells a word wrongly with the left hand on purpose, looks roguishly for a moment, and laughs, and then strikes the left hand with the right, as if she wanted to correct it.

Dr. Howe wrote to me as follows, in September, 1839, about his pupil, who is now ten years old:—"The little Laura now possesses a great stock of words, which increases rapidly, as she has an inextinguishable thirst for knowledge, and incessantly asks for the names of things, and invents new sentences. Some of these sentences are very remarkable, and, being written down by a judicious and faithful teacher, they are preserved for a future time. I am of opinion that the observation of the unfolding of her intellectual powers will throw much light upon many psychological questions. She has lately began to learn to write with a pencil. She can now not only write her own name, but also short sentences composed by herself. She has apparently arrived at the power of communicating, in this manner, the thoughts of her own mind to the mind of another. No words are capable of giving you an idea of this attractive child, whose countenance beams with mind, whose motions are refined and graceful, who is always zealously employed in learning something new, while passing her delicate fingers over some new and surprising object; or else she sports among her blind fellow-sufferers as soft as a lamb. The fineness and sharpness of her sense of feeling can be equalled only by the wonderful accuracy and retentiveness of her memory. All these things, however, are only physical*, and are to be found in Julia Brace, and, perhaps, in other blind persons.

* Surely Dr. Howe is mistaken here; neither the goodness of her memory, nor the intelligent expression of her face, can be considered merely physical.—TRANSLATOR.

But that a girl perfectly blind, dumb, and without the sense of smell from her childhood, should begin to be educated at the age of eight, and in two years should be able to use an artificial language, and compose and express sentences, is wonderful and unprecedented, and shows the powers and resources of the human mind.* —*Zeitschrift für die gesammte Medicin*, Jan. 1840.

ON THE FORMATION OF CANCER OF THE VEINS,

AND THE POSSIBILITY OF COMMUNICATING
CARCINOMA FROM MEN TO ANIMALS.*

By DR. B. LANGENBECK, of Göttingen.

LATE investigations, and especially those of Carswell and Cruveilhier, have shewn that the occurrence of cancer within the veins is by no means rare; and the latter has found it so frequently, that he has come to the opinion that all cancers are originally developed in the venous capillaries. But, however frequently the veins may be the seat of carcinoma when the uterus is affected with that disease, yet in some cases they are undoubtedly quite healthy, and I therefore cannot coincide with Cruveilhier's opinion. I am rather inclined to regard the frequent occurrence of carcinoma in the veins as in most cases something secondary, like phlebitis, a disease which is also frequently joined with carcinoma, and especially with carcinoma of the uterus.

But, with however little confidence it can be at present held, that the capillary veins are the seat of origin in all cases of primary cancer, they are still very frequently to be regarded as the seat of the development of secondary carcinoma, and I would even hold, that in all cases in which a primary cancer exists, or has existed, and in which secondary cancer appears in some other part of the body, it is constantly developed from the capillary vessels, (I will not say veins).

The answer to the following questions appeared to me of the highest importance. How does the matter of cancer get into the veins, and how does cancer develop itself within these vessels? One might expect either—1st. That the disease forms as a cancerous degeneration of the walls of the veins, which are, no doubt, subject to the affection like all other tissues. But against this idea is the fact, that in almost all cases of cancer of the veins, the

disease is connected with the internal as well as the external surface of the vessel: or 2nd, we might conceive that the cancerous matter grows from without inwards into the cavity of the vein; but this could account only for those cases in which the veins immediately adjacent to a cancerous mass are diseased, but not for those in which the veins at a distance are affected: or 3rd, it might be, that separated fragments of a cancer pass into the veins destroyed by ulceration, and accumulate at some part of their interior; but in this case it would be difficult to imagine how the masses of cancer within the veins should (as they often evidently do) possess vessels.

The author considering each of these modes of explanation equally unsatisfactory, proceeds as follows. The cancerous matter which I have found in the veins lies in part quite loosely in them, without any connection with their walls, and is in part slightly adherent to their internal surface; and lastly, in part it forms one mass with their walls, which are in like manner converted into carcinomatous tissue. The origin of these differences remained for a long time obscure to my mind; but two cases of incipient carcinoma of the lungs, which were developed secondarily to carcinoma of the uterus, completely explained it. I convinced myself that the development of the cancer of the veins depends on that most remarkable property which the minutest cancerous molecules, the microscopic cancer-cells, possess, of developing themselves into cancerous tumors even when they are completely isolated, and without any organic connection with each other in the circulation.

The development and the growth of carcinoma, as well probably as of all morbid tissues connected with the organism, depends, as is well known, on the growth of simple cells, and takes place according to the same laws which Schleiden first proved in plants, and which Schwann has shewn to obtain in the normal animal tissues, and Müller in many morbid structures. The analogy of the mode of growth of all organic structures, which is so clearly proved by the investigations of these authors, is remarkably confirmed by the fact, which I have observed, that the germ-cells of a cancerous tumor, introduced separately into the fluids of the body, or passing accidentally into the circulation, may develop themselves independently, or in any part of the capillary system, into carcinomatous tumors, just as, in the lower plants, any cell separated from the plant may continue to grow independently.

Both the cases from which the author was enabled to draw this conclusion were cancers of the uterus. In one, nearly the

* The author by the terms *cancer* and *carcinoma*, appears to mean the whole family of malignant tumors; his cases relate chiefly to the medullary or encephaloid species.

whole uterus was destroyed by ulceration, and a recto-vaginal fistula had formed. In the other, only the cervix uteri was destroyed, and it was converted into an ulcer with callous margins. In the bodies of both patients, there were found in the uterine and pelvic veins light yellowish-red granular coagula, (the *matieres cancéreuses* of Cruveilhier) consisting of soft fibrine, coagulum, pus-globules, and small cancer-cells, whose diameter was twice as great as that of the pus-globules. The greater part of the coagulum was formed of very small, rather long, rounded transparent granules, half as large as blood-globules, and in every respect similar to the finely granular matter which one finds in the simple microscopic cancer-cells, so that I could not but regard them as the contents of destroyed cancer-cells set free. The iliac veins, the inferior cava, and the right side of the heart, were full of dark fluid blood; in that in the veins I found with the microscope granular cells with very distinct yellow-coloured nuclei, and a quantity of the fine granules which formed the principal part of the coagula in the hypogastric veins. In the blood of the right side of the heart I detected, with the naked eye, yellowish-red soft coagula, consisting of the same microscopic elements as the coagula of the pelvic veins. When I opened the pulmonary artery from the right side of the heart, I found in it the same reddish-yellow granular coagula as in those veins, only that here they appeared much firmer, and in the finer branches of the pulmonary artery were here and there distinctly united with the inner surface of the vessels. In the larger branches of the pulmonary artery, these coagula lay completely free, and partly filled the cavity of the vessel; but the finer the divisions of the artery became, the more completely did the vessels seem blocked up, and the more intimate was the union of the coagula with their walls. Under the microscope, these coagula were found to consist almost entirely of large cancer cells, of which the majority seemed five or six times as large as blood globules, and which were in no respect distinguished by their form from the cells in the tissue of the cancer of the uterus.

These coagula consisting of particles of cancer in the pulmonary artery, admit of a two fold explanation. Either, 1st, they were merely dead aggregations of separated particles of the cancer of the uterus, which had passed into the circulation through the ulcerated and open uterine veins, and had proceeded with the blood through the right side of the heart into the pulmonary artery, and accumulated in its smaller branches, (but to this view the circumstance is opposed that the uterine and hypogastric veins contained exactly similar

coagula, but which were much softer than those in the pulmonary artery, and had nowhere any connection with the walls of the vessels, and were composed of a number of smaller cancer-cells, and only in part of nuclei); or, 2ndly, these coagula were true cancers in the course of development and vital growth, whose form only appeared somewhat modified by the adjacent parts, the walls of the vessels. In favour of this view was the fact of the more complete formation of the cancer-cells in these coagula in the pulmonary artery, and their complete union with part of the walls of the vessels. Besides, when I traced the coagula into the minutest branches of the pulmonary artery, I came upon small flattened roundish cancers at the surface of the lungs, just under the pleura, into which I could trace small branches of the pulmonary artery completely filled with cancerous matter. In the neighbourhood of these incipient cancers, the coagula were so intimately united with the walls of the vessels, that they could not be distinguished from one another, but presented beneath the microscope a homogeneous cancerous tissue. But when the vessels passed into the small cancerous masses, then they completely lost their cylindrical form, by the growth of the cancerous structure through their walls. With the exception of the small cancers, of which there were ten or twelve in each, the tissue of the lungs was perfectly normal, though from the obstruction to the pulmonary circulation very œdematous.

I think it is very probable that, in most cases, cancer of the lungs develops itself within the branches of the pulmonary artery, from molecules of cancer which have passed from some primary cancer into the venous blood. Cancer of some other part of the body almost constantly precedes its development in the lungs; and the cases of primary cancer of the lungs are extremely rare. Bayle never saw but one, and Bouillaud only two; and Andral has never seen a case in which the lungs alone were affected.

That the minutest portions of a cancerous tumor, the cancer-cells, still possess the power of developing themselves independently into cancerous tumors, though separated from their original stock, the primary cancer, and planted on a foreign soil, can scarcely appear strange when we remember that the germ of the ovum, itself nothing but a cell, and, in fact, remarkably like a large cancer-cell, separates after conception from the ovary, to be developed independently in the uterus, or quite away from the maternal body. Like the germ of the ovum, every individual cancer-cell must be regarded as an organism endowed with vital power and capa-

bility of development, which, even when separated from all organic connection with its original soil, can yet continue to grow independently, so long as it is in the neighbourhood and under the influence of living organic tissues.

It was of considerable interest for me to determine whether cancer-cells, introduced into the circulation of an individual of a different species, would develop themselves into cancerous tumors in the capillary vessels. The endeavours of Alibert to produce cancer in animals and men by inoculating them with cancerous ichor, were, it is well known, ineffectual; and I repeated the experiment several times, both in dogs and rabbits, in vain. But if my observations on the development of cancerous tumors from simple cancer-cells were correct, it was clear that the seeds of the disease were in them only, and that a communication of cancer could be effected by nothing but them. This being assumed, it was explicable why the experiments of inoculation with the ichor had failed; for in it, as it is commonly taken, no cancerous molecules are ever found. I therefore determined to introduce some cancer-cells from recently extirpated human cancer, into the circulation of animals. Several rabbits, into whose external jugular or saphena veins I introduced fluid from fresh carcinoma, died between 12 and 24 hours after, from a remarkable obstruction which the injected fluid had caused in the capillaries of their lungs; for all died with dyspnoea, and all their lungs exhibited a considerable number of small ecchymoses. But, contrary to my expectation, the following experiment on a dog was important in its results:—

I took eight ounces of blood from the femoral artery of a large, strong, two-year old dog, and removed its fibrine by stirring. I then took about half an ounce of a whitish cancerous fluid, which had been scraped from the cut surface of an enormous medullary cancer, just removed from a young man's arm, and carefully purifying it from all the pieces of the tumor that were mixed with it, I mixed it with the defibrinated blood, and injected it into the femoral vein of the same limb. Two days afterwards, the dog was ill and feverish, but had no affection of the respiratory organs, and in eighteen days he was quite well. Some time afterwards, he began to grow very thin, and on the 10th of August I killed him by pithing. On opening the chest, the lungs were found apparently healthy; but on the anterior surface of their upper lobes there were two or three clear-bluish, flattened, and rounded tumors, of the size of a lentil, which were remarkably like the small cancers of the human lung described above, and, under the microscope,

presented the texture of cancer. In the substance of the middle lobe of the left lung there was a large, hard, circumscribed tumor, of the size of a large field-bean. The pulmonary tissue around it seemed quite healthy; but, on its cut surface, it presented all the appearance of a cancerous tubercle, consisting of a hard, homogeneous, clear-bluish substance, in which there were here and there points of blood, which, under the microscope, looked like convoluted capillaries.

Now, as this tumor possessed a peculiar and definite tissue, and was organised with blood vessels, it could not possibly be a mere accumulation of the cancerous matter injected into the blood, but it must, if it were of a cancerous nature, have been formed by the growth and continued development of the cancerous molecules. The microscopic examination of the fresh tumor left no doubt whatever of its carcinomatous nature. It consisted of large, clear, juicy fibres, of the thickness of primitive muscular fibres, between which cells of 1-100th of a line in diameter were thickly scattered. In the clear fluid which could be squeezed out of it there were smaller cells, partly of the size of blood globules, and partly only half as large as them; and, besides, it contained a quantity of fat. The same microscopic elements were found in the medullary cancer of the humerus from which the injected fluid was taken, and the similarity in structure of the two tumors could not be doubted when they were compared with each other. The cancer of the lungs in the dog was distinguished from that of the upper arm of the man only by its greater hardness, its larger fibres, and the large, dark, granular cells, with distinct nuclei, which were here and there scattered in it, just as I have so often seen them in scirrhus of internal organs, though never in medullary tumors. The cancer-cells, therefore, appear to be a new development from the injected substance: and hence, I think, they confirm the idea, that the medullary and the hard cancer are only different forms of essentially the same disease, and may pass the one into the other.

In the great frequency of cancerous diseases, it will be an easy matter to repeat and vary the experiments I have instituted, and, without doubt, they will succeed alike with all the varieties of cancer. It is still to be determined, how far the vitality of the cancer-cells is dependent on the life of the organism; and whether cancer-cells, taken from the cancerous tumors of a dead body, can develop themselves into carcinomatous tumors, as well as those from cancerous tumors just removed from the living body, and still warm.—*Schmidt's Jahrbücher*, Bd. xxv. hft. 1, p. 99.

ADMISSION OF SPECIALITIES INTO
THE HOSPITALS OF PARIS.

THE following case, and the remarks contained in the protest to which it has led, afford a good confirmation of the observations which we lately made, in reference to the impropriety of establishing separate institutions for the treatment of certain special diseases:—

The French medical journals announced last February the nomination of M. Leroy d'Etiolles, to a place at the Central Office of the Hospitals, exclusively appropriated to the external treatment of diseases of the urinary passages; an office created by the general council for hospitals, and given to M. Leroy without concours.

As soon as the surgeons of the several hospitals and of the Central Office became acquainted with the new appointment, they took the opportunity to protest against the introduction of specialities into the service of the hospitals. To their protest, however, which obtained an unanimous assent from all the officers of these institutions, the council general answered that the nomination of M. Leroy d'Etiolles having been determined on, and signed for a month, could not be revoked; and he has therefore retained his office.

We pass over the remarks of the editor of the journal, from which we extract this notice, (the Archives Général de Médecine, Mars, 1840,) which are rather directed against the breach in the system of concours than against the system of specialities, and present the following abstract of that part of the protest which relates to the latter subject:—

The Hospital-surgeons of Paris being informed that M. Leroy d'Etiolles has addressed to you a request to be admitted without concours among the surgeons of the Central Office, and to create for him, in that establishment, a special department for the diseases of the urinary passages, have thought it their duty to submit some observations to your intelligence and justice.

In the first place, they ask themselves what are to be the objects of the new department? are they to be the special treatment of stone by lithotripsy, or is it to include all the affections of the urinary passages? The first supposition cannot be admitted, for it can never enter into any one's mind that so serious an operation as lithotripsy should be undertaken, without a consultation, on patients who have come on foot, and who are obliged at once to return home, and remain there, left to all the chances of the accidents that may come on. Nor is the second supposition more favourable to the appointment that is requested; for if some of the diseases of the urinary passages are sufficiently slight to be cured by the means

administered after a single consultation, there is no need of changing the system already established. Every day, in every hospital, and, therefore, in every quarter of Paris, assistance of this kind is afforded to sufferers, by surgeons who have stood the test of concours, and who possess the confidence of the administration. We rejoice to think, that with these two guarantees, it cannot be supposed that the treatment of the diseases of the urinary passages is neglected in the hospitals, or that it can be better known elsewhere. Need it be added that by means of the assistance thus afforded in every district of the capital, every patient receives, without inconvenience, and almost without loss of time, the aid which he requires. * * * * But it is our duty to add that the extent to which specialities are being carried in the hospitals of Paris, is altogether contrary to the interests of the patients and of science. We know with what prejudice the question of specialities generally is judged of in the world. In vain do the great majority of men of science declare themselves against it; the world dares not deny their competency to judge, but it accuses them of partiality. But it must be said that the reasons on which our convictions on this point are founded, rise to a period beyond the present time; the whole history of surgery deposes that the art has constantly suffered by being broken up, and that it has been saved only by great minds remodelling it in its perfect and entire state. In the middle ages there were a multitude of specialities; some for the eyes, others for the stone, and so on. The cutters for hernia have left a fearful reputation; the bone-setters were reckoned among the scourges of the provinces. It was at Paris, and especially in the hospitals of Paris, that, by the effort of time and the genius of some few men, this brilliant synthesis of our art was effected; it should not be for the same hospitals to give the signal for fresh anarchy. It vain is it pretended that the times are not to be compared; without going further back than the second half of the last century, there were not wanting then special surgeons; and if one asks, what they have effected, one too often finds nothing but a confused assemblage of formulas for secret remedies, supported by all the forms of charlatanism.

No doubt there are men, to whom such reproaches cannot be applied; but we know also that really powerful intellects never consent to confine themselves within the narrow circle of specialities; and that surgery owes none of its progress to those who have studied but one of its branches. The restorer of ophthalmology was Scarpa; the surgeons who have done most for the treatment of hernia, are Scarpa, Astley Cooper, Dupuytren, not to mention any

of our colleagues still living. The practitioners who have thrown most light on the diagnosis and therapeutics of the diseases of the urinary passages, are Chopart, Desault, Dubois, Boyer, &c.

We hope, therefore, that the council-general of the hospitals will be pleased to refuse the creation of a new place, and thus to oppose a useless innovation, injurious to the interests of the patients, and prejudicial to the progress of surgery.

COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

A LETTER signed "M.D. Edin. et Leyden," which appeared in your journal a few weeks since, makes two assertions; first, that the College of Physicians, London, has the power of conferring the title of Doctor of Medicine; secondly, that the College has declared that it will grant the above title to all who may become its licentiates or extra-licentiates. The reply in your last number has clearly and triumphantly shewn that the College has no power whatever to confer medical degrees; but the assertion made by "M.D. Edin. et Leyden," that the College has declared that it will grant the title of Doctor to its extra-licentiates, remains still uncontradicted. As this assertion is unjust to the College, and has no foundation in truth, I trust you will permit me to prove it to be so.

The College, in its circular of Dec. 22d, 1838, states that, "it is prepared to address by the same application" all who have passed the various strict examinations for licentiate "before the Censors' Board," whether they have a degree or not; but it has not announced that it will bestow the same title on the extra-licentiates who go through a very trifling examination before the elects of the College; therefore it is evident, that the extra-licentiates have no ground whatever for assuming to themselves the title of doctor, in consequence of their extra license; and, consequently, that it is a palpable mis-statement on the part of your correspondent "M.D. Edin. et Leyden," to assert "that the College do grant the degree and title of Doctor of Medicine to those who pass the examination for licentiates or extra-licentiates" of that Corporation.—I am, sir, &c.

M.D. Oxon.

May 10, 1840.

[We believe that our correspondents of

this and last week are both mistaken, and that the College of Physicians has precisely the same right to make Doctors in Medicine as the Inns of Court to make Doctors in Law. It is, however, the affair of the Fellows of the College of Physicians, not ours; and to them we leave it.—*Ed. Gaz*]

TESTIMONIAL TO

W. FERGUSSON, ESQ.

Professor of Surgery in King's College, London.

ON Monday, the 4th instant, a splendid testimonial was presented to this gentleman, in his class-room, Infirmary-street, on the occasion of his leaving Edinburgh, to enter on the duties of Professor of Surgery in King's College, London. The tribute consisted of a large, massive, silver tray, of exquisite workmanship, the gift of a numerous body of the medical profession of this city, and several other friends; as also of a chaste and beautiful claret jug, of the same material, being the gift of the students who attended Mr. Fergusson's class during the past session. Both those pieces bore suitable inscriptions. Professor Lizars was deputed to present the first; and Mr. Adams, the testimonial of himself and his fellow-students: which they accordingly did, after interesting and appropriate addresses.—*Caledonian Mercury*.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

—
FRACTURES continued.—General treatment—
Nasal bones—Malar bones—Superior maxillary bones—Inferior maxillary bone.

Treatment.—With respect to the means for removing the patient from the place where the accident has been received to the bed upon which he is to remain while under treatment, I shall presume that the intelligence of the practitioner will enable him to do what is best under the particular circumstances of each case. The bed should not be too wide, or it will be found inconvenient to the medical attendant in dressing, bandaging, and so on. A feather bed is too soft, and too easily yields to the weight of the body; a mattress will answer the purpose better. At all events, if a feather bed be used, a good mattress should sustain it. In many cases boards will more completely attain the object. But whatever care may be bestowed on the bed, it ends by becoming unequal, and, from other causes, it also becomes necessary to transport the patient to another. Many means and many beds have been invented to overcome these inconveniences, but they are not completely removed, and such beds cannot be used in the treatment of the majority of cases.

There are three principles to be kept steadily in mind in the treatment of fractures: the first is to procure exact reduction; the second is to retain the parts in proper contact so long as may be necessary for consolidation; the third is to prevent

the development, or to relieve ulterior accidents. It is true that in some cases there is no displacement; then the first principle does not apply. Reduction is commonly obtained by extension and counter-extension, to which may be added coaptation. The first consists in dragging upon the limb by its inferior extremity, for the purpose of producing as much elongation as it will admit of, the fragments being properly reduced. By counter-extension we understand the means which are used to maintain the trunk, and the part of the limb above the fracture, in a state of immobility. By coaptation we mean the reduction of the fragments, by the application of the hand upon the fractured point.

Extension and counter-extension should be applied as far as possible from the fractured point, for the purpose of avoiding compression, which often induces in the muscles spasmodic contraction, by which the displacement may be increased, and reduction rendered more difficult. Thus, in a fracture of the leg, the extension is applied upon the foot, counter-extension upon the thigh; in fracture of the thigh, extension is applied upon the leg, counter-extension upon the pelvis.

Pott recommended a different course: he placed the limb in a state of semi-flexion, before attempting reduction, and made extension and counter-extension upon the extremities of the bones. His object in this was to place the limb in such a position that all the muscles which are inserted in the fractured bone may be relaxed, so as to offer no obstacle to reduction. The method of reducing fractures, by placing the limb in the semi-flexed position, is not so free from objection as some persons believe. What is gained by the relaxation of one set of muscles, is nearly counter-balanced by the tension of others. Still, if in the particular case we can by semi-flexion relax the more power-

ful, a manifest advantage is obtained. In fractures of the leg, the muscles of the calf are powerful in producing displacement; a semi-flexed position in which they are relaxed, would certainly be the most favourable to reduction, and also during the after treatment.

In the reduction of fractures, machines for making extension are exploded; the hands are almost always found to be sufficient. Always extension should be gradually and steadily made; if it be made suddenly and violently, the muscular fibres may be ruptured and otherwise injured. It is desirable, during the time extension is making, to endeavour to distract the patient, to direct his attention to something unconnected with the business of reduction, as it tends to lessen muscular contraction at the part. When extension has been carried far enough, the hands should be applied to the part. It may happen that the attempts to reduce a fracture will be unsuccessful, either because extension has been too suddenly applied, and spasmodic action excited, or because muscular contraction is produced by pain or irritation. In the first case the remedy is easily applied; in the second it may be necessary to bleed or give opium.

Reduction, however, is not the difficulty most commonly experienced in fractures, but the power to maintain it until nature shall have provided against displacement. The means commonly employed for the purpose, are a proper position, rest, bandages, splints, and a great variety of apparatus. It is of great importance to place the patient and the limb in a convenient position; supposing the injury to affect the leg, it must be equally and comfortably supported along its whole length; if it be applied injudiciously, two accidents may happen, a new displacement and inflammation, or gangrene at the points where pressure has been so made. Whatever be the position we give the limb, whether semi-flexed or extended, it must be maintained at perfect rest during the time necessary for consolidation. If motion be experienced at the fractured point, the formation of callus will be interfered with, and the cure may be interrupted. Ordinary bandages are comparatively useless, as means of maintaining quiet; but they are of use in supporting compresses, upon which cold or other applications may be made. To maintain reduction, pillows, junks, splints, and certain other apparatus, are employed. The objection usually made to junks is that they are cylindrical, too narrow, and too easily displaced; but this objection might be removed, for the cylindrical form is not absolutely necessary. Splints variously modified are most commonly employed for maintaining the

reduced fragments; they should be strong enough to offer sufficient resistance, and long enough to remove constriction from the part. They are made of wood, bark, leather, iron, pasteboard, and other substances. They may be as long as the injured bone, or as the limb itself; they should not be directly in contact with projecting points. In some fractures a single splint is used, in others two, in others three, or even four. Pasteboard splints are used in certain cases, where the consolidation is long about. They are always moistened before they are applied; they thus adapt themselves perfectly to the form of the limb, and in drying become perfectly firm and hard, and partake much of the character of the immoveable apparatus. But probably the best form of paper splint is that which is formed by applying upon the limb a certain number of layers of brown paper, between each of which a layer of paste, gum, dextrine, or some similar substance is applied, each layer becoming dry before another is applied; this becoming perfectly modelled upon the limb, can, therefore, make no unequal pressure, and may be removed at will.

Whether we apply the one or the other, (taking care that it is neither too lightly nor too tightly bound,) we should interfere with it as rarely possible. Still it must be watched, tightened if necessary, and the apparatus should even be removed to ascertain whether the fragments have been properly sustained; this should be done at the end of ten days or a fortnight from its first application, and again before the apparatus is dispensed with. It is practice alone which can teach us as to the constriction which it is necessary to apply. It often occurs, especially in fractures of the leg, that the patient experiences during the night spasmodic contractions, by which he is awake, by which the apparatus may be somewhat deranged, and the fragments displaced; this must be particularly attended to. Some surgeons recommend an almost daily removal of the apparatus, to be assured that all goes well. This practice I decidedly object to; it is opposed to that important principle—the necessity of absolute rest. Another treatment, the opposite to that, is the “immoveable treatment,” in use from a very early period among the Arabs and Greeks, and employed in Switzerland, Spain, and other countries. In France the principle has been largely tested by Larrey. In this case the apparatus is not removed from the time of its application to the moment of cure, in conformity with that principle that the more complete the repose the more rapid will be the consolidation. The apparatus of Larrey, which is applied

equally to compound and simple fractures, is formed by placing a couple of junks at the sides of the limb; they are secured by means of linen cloths of the length, or rather more, of the fractured bone; these are wound around the limb, and secured by ligatures. The whole apparatus is saturated with a mixture of white of egg, camphorated spirit, and goulard water. At the end of twenty-four to thirty-six hours the apparatus, so applied, becomes perfectly hard, and, as it were, a solid piece: to attain this quality, it must not, of course, be covered up, or it remains soft. Once dry, it effectually prevents displacement, being moulded on the part.

Certain objections, however, are made to this plan; that, as thirty or more hours pass before the apparatus is firm, the fragments may during that time be displaced; that, if applied when there is much tumefaction, when that subsides, there must be a considerable interval between the apparatus and the limb: there is clearly truth in these objections, but they are not weighty. In any mode of treatment, it is not commonly during the first three days that displacement occurs; it is later, when the patient gets restless; it is rarely that the subsidence leaves a very great interval, and by that time the callus has acquired some power; if there were force in this objection, it might be obviated by allowing the swelling to subside before the apparatus is applied. And against any theoretical objection, as to gangrene, and so on, the results of the treatment may be opposed. Its advantages must be obvious; it admits of moving the patient from his bed by the third day, and gets rid

of the inconveniences attendant upon confinement. The method of Larrey has been much simplified by Seutin and others. The method of Seutin was to place around the limb three, four, or more layers of bandaging, between each of which was a layer of starch. When dry, this constituted a firm splint exactly moulded upon the leg. The strip of paper plan which I have alluded to is a modification of the same system. So also is the mode employed in very early times, and revived by Dieffenbach, of surrounding the limb with plaster of Paris.

I am of opinion that in a considerable number of cases it is desirable, from week to week, to ascertain the condition of the part; at the same time I decidedly object to a frequent interference. Therefore it is that I am disposed to object to any system which places difficulties in the way of such supervision; and the plans of Larrey, Seutin, and Dieffenbach, certainly are open to this objection, though, at the same time, I readily admit that, in a large number of cases, they are unexceptionable. But I look to the strips of paper or papier maché method as the one which ought to be most generally used.

We must now consider another system of treating fractures which has been, within a few years, much employed by Santer of Constance (*Annweisung*, &c. 1812, 8vo. fig.) and by Mayor, of Lausanne (*Memoire sur l'Hyponarthecie*, 1821, 8vo.) This method consists in the use of an instrument like one side of an old fashioned scales—that is, a flat oblong board suspended by four cords at its corners; upon this board a pillow is placed,

and it is raised or lowered to the required elevation by pullies. The board should be two or three inches longer than the limb, and from six to nine inches wide—adapted to it is a small mattress stuffed with horse-hair, chaff, or other substance, which must be thick enough to prevent the possibility of improper pressure. The limb being placed upon it, it is surrounded by a broad piece of linen, which is also passed around the apparatus, so as to prevent the one moving without the other. If the fragments tend to ride, this may be prevented by making extension, and securing both extremities of the limb to the extremities of the board. This apparatus is susceptible of various modifications by which it may be adapted to the different limbs. Munaret has proposed a modification which seems to me a decided improvement. He substitutes for the board a gutter of painted iron adapted to each limb. This is unquestionably a very valuable invention; it admits of making

the necessary applications to the part without in any way disturbing it, and it allows of a changing position without inconvenience. Still it is doubtful whether this system will get into general use; for I cannot divest my mind of the conviction that this mode, as well as a still more unsafe one lately recommended in this country, affords more facility for displacement than the other methods of which I have spoken.

The fracture has been reduced—the means of preventing displacement are applied, but there are other circumstances to be attended to. You must anticipate or watch the advent of accidents—consequences of the injury. If the patient be young or vigorous, and there be much tumefaction, it may be advisable to bleed; but this should not be heedlessly done, nor as a matter of routine, because it is probable that callus is as much more promptly formed as the circulation is more energetic, and the strength good. As soon as inflammatory symptoms begin to subside, the

diet should be improved. If there be constipation, which is commonly the case, it must be relieved by the gentlest means, because a frequent call to stool will be likely to displace the fragments. When the consolidation is completed, it is always well to allow a couple of days to pass after the removal of the apparatus before the limb is used. There is always a certain feebleness and rigidity of the limb, depending, to a considerable extent, upon the splints and bandages which have interfered with the circulation, and have prevented muscular action. This state is relieved by frictions, baths, and douches; but the effect is not soon got rid of. Occasionally a very uncomfortable symptom is long felt after a fracture; a pain is experienced at the part after walking; and sometimes the muscles of the part act spasmodically. I have known two cases in which this state was very troublesome; but it yielded at last to blisters and an issue.

COMPOUND FRACTURE.—In compound fractures the treatment is different; the tumefaction and disorganization of the part may be great, and may require a very decided course of treatment. But here, at the threshold, we are met by a much debated question—should we at once proceed with the reduction, or should we wait, until by antiphlogistic means this condition is abated. It is thought by some persons that the displaced fragments are a constant source of annoyance and irritation; others believe that the violence which may be done in attempting reduction, will be more injurious than useful, by greatly increasing the inflammation. Like all other similar questions the difficulty is got rid of by taking a middle course, sometimes following one, sometimes the other; and it is difficult to lay down a rule on the subject. There is another point to which I must direct your attention, phlyctenæ are often seen in cases of fracture; they contain a yellowish serous fluid, sometimes it is brown or bloody, but they do not indicate the existence or even the approach of gangrene, they are only signs of contusion. You must not remove the pellicle which covers them or they will be painful; they may be punctured with a fine needle, and covered with simple dressing. If the integument be disorganized, the inflammation will excite suppurative action; if it establish a communication with the fracture, it may be serious; if not, it may be treated like a common wound. In the latter case it will be wise to limit the inflammatory action as much possible, or it may interfere with the progress of consolidation. When the wound communicates with the fracture, if it be the result of a cutting instrument, uncomplicated with

hæmorrhage or extravasated blood, we should endeavour to procure immediate union, and reduce it to the condition of a simple fracture; but in a majority of cases the result will not be obtained, and long suffering will be the consequence. It is not long since surgeons thought compound fractures cases for amputation; in the present day we regard them differently. And, although in this metropolis, the wholesale result may be very unfavourable, it is not the case in the provinces. If the wound have been occasioned by a fragment of bone, and the wound be not large nor much jagged, we may attempt union. If the fragment of bone be large and protruding, and the fracture transverse, it may be reduced, and we may pursue a similar course. If it cannot be reduced, the wound may be enlarged longitudinally, in the course of the vessels and nerves, as affording the best chance of avoiding them. If the extremity of the fragment be reduced, it will be wise to remove it with the saw, being careful to protect the soft parts; if there be many loose fragments, much after mischief may be prevented by removing them; and in either case bring the parts together, so as to afford the best chance of union. If the wound has been caused by the passage, over the limb, of a cart or other wheel, or indeed any similar contusing body, the bone will probably be comminuted, and the soft parts may be so much injured as to render immediate amputation necessary. Do not, however, proceed to amputate until you have well examined the injury, and estimated the probable power of repairation; and here a long experience is the safest guide. It is astonishing what an extent of injury may be repaired in young people. In cases where the contusion is very severe, the application of cold or iced water for the purpose of subduing inflammatory action, should not be heedlessly made; it may induce gangrene; if the contusion be violent, it is a most valuable application. It may be necessary to bleed generally and locally, for the purpose of subduing the mischief, but in doing so, you must not lose sight of my former caution. If the separation of a considerable slough lay bare a portion of bone, the suppuration will be abundant, the periosteum will be bathed in pus, and the probability of necrosis great; dressing should be frequent, and dry lint applied upon the part, to absorb the pus; with all our care it may burrow or take the course of tendons, and abscesses be developed at a distance. In this case it is necessary, by bandaging, position, and counter-openings, to procure the escape of this fluid. Often, after a long time, spiculæ of bone, necrosed or otherwise, will continue to be thrown off. It very often happens, that after a period

of many weeks, a time arrives that many patients are lost. A fragment of bone in the thigh, for instance, has remained in contact with the artery; at last it has ulcerated it, and a secondary hæmorrhage occurs. Pelletan describes such an occurrence at the end of seventy-five days. Or the suppuration may be so profuse as to exhaust the patient; or it may infect the system, and typhoid symptoms will be developed, and it may then be too late to amputate. To succeed in these cases, it must be practised immediately after the injury; when the inflammation is followed by gangrene, when suppuration has become so excessive as to occasion hectic, by which the life of the patient is threatened, it is often too late.

Supposing the fracture to be complicated by the wound of a large vessel, if there be no external wound, enormous tumefaction will be soon developed. This tumefaction will not be circumscribed, and the integument will rapidly acquire a violet colour. If a vein be wounded, after a short time it ceases to make progress, and the fluid may be absorbed, or it may be removed by incision; sometimes, if left to itself, it has terminated in abscess. If an artery be wounded, the extravasation continues, the tumefaction increases, and commonly a pulsation may be distinguished in it, isochronous with the motion of the heart. In this case we are rapidly threatened with gangrene. Formerly surgeons were accustomed to amputate, but the success was not great; and of late, the practice has been successfully introduced, of placing a ligature on the artery, at a distance from the injury.

But seldom it happens that nervous cords are injured in these accidents; and probably these are cases in which, now and then, we see tetanus developed; if the injury have been sufficient completely to destroy the nerve, we may have paralysis.

Larrey and the Spanish surgeons apply the immoveable apparatus in case of compound fracture, and allow them to keep their place up to the complete consolidation; no matter how much pus may be exhaled or how offensive may be the apparatus. There can be no doubt that to the military surgeon it is a matter of the first importance that the mode of treatment should afford the greatest possible facility for removing the patient; and in the field this treatment may be the best, but certainly it should be modified so as to admit of frequent examination and dressing; for instance, the Arabs cut out a portion of their apparatus, corresponding to the wound.

When a fracture is very near an articulation, it is wise to move the limb from time to time, to guard it against the chances of ankylosis.

Callus.—It is now time to consider the formation of that substance by which the fragments are preserved in contact, as well as that by which permanent union is accomplished. This matter, termed callus, is formed around the fragments in the following manner:—When a simple fracture happens, there is always a slight, often a very considerable, displacement, and that displacement must occasion a certain quantity of injury to the soft parts, and rupture a certain number of vessels, from which blood, in small or large quantity, will be extravasated, and will coagulate around the fragments. Soon this coagulum is broken down, and its more fluid part is absorbed; the vessels then pour out another kind of fluid, lymph; this lymph is poured into the injured parts as well as those in their vicinity, and a homogeneous mass, of a bulk corresponding very much with the quantity of inflammation, is formed. This mass soon becomes pervaded by vessels, which deposit here and there osseous matter; these increase in number until the whole mass becomes firm and gritty. A similar matter penetrates to a certain extent into the medullary canal, acquires a similar consistency; and thus are formed two natural obstacles to further displacement, an internal plug and an external splint. At first the deep-seated muscles or tendons, and other organs, are implicated in this external mass, gradually it lessens in bulk, and these organs are restored to freedom; as it lessens in bulk, it increases in density, and effectually prevents displacement. As soon as this provisional medium of union is formed, the patient may use the limb without apprehension. But still, at this time, although the restoration has proceeded thus far, although the new periosteum has become continuous with the old, if we saw longitudinally through the callus we shall find that the medium of union between the fragments is yet incomplete; and it is not until that is perfectly accomplished that the bone is reduced, by the absorbents, to its proper limits.

If the case be one of compound fracture and suppuration be established, the process of reparation varies; the fragments are covered with granulations; as soon as suppuration ceases they coalesce, lymph is found upon their surface, and union is completed; this granular mass is a matrix for the reception of calcareous matter, which gradually renders the mass of a bony consistency.

In a common case of simple fracture, the mass of callus does not acquire much density before the end of three weeks or a month; therefore it is we do not allow a patient to use the limb until after that period. But numberless circumstances occasion variations in the time of its occur-

rence. It is sooner brought about in children than in adults, their system being more vascular: thus, in a child, a fracture may be consolidated in twenty days, whilst the same result would not be obtained in an aged person, before the sixtieth to the seventieth day.

Fractures are more speedily enured in the upper than the lower extremities; this, of course, depends upon the influence of position upon the circulation.

Under many circumstances, the process of reparation is retarded; sometimes in a person apparently in the best health, this feature is observed. But there are circumstances under which these things are frequently seen: if you bleed and keep a patient on vegetable diet during the time of treatment, consolidation has been prevented. During pregnancy, the process is often retarded, but this is not an unvarying effect. Scorbutus exercises a very decided influence in opposition to consolidation. There is a species of bastard scorbutus, which sometimes occurs during the treatment of fractures, and exercises a similarly baneful influence. Syphilis and rickets occasionally produce similar effects. It is asserted that cancer exercises the same deleterious influence, but I know no good facts to support this opinion, though it is probably correct.

There are other causes more decidedly local in their nature; among these a want of coaptation in the fragments is the most marked, and even in this there is much caprice. Van Swieten knew a case in which four inches of the tibia had been removed, and its place supplied by a hard body, without any shortening of the limb. I have known a case in which, in a young man, five inches had been removed with a similar result. Lamotte mentions a similar case, in which six inches had been removed. I have known a case in which a large portion of the clavicle was removed and similarly repaired; but usually an artificial joint, or a fibrous representative, is the result. The absence of the necessary nutrition in one of the fragments, is another cause; possibly intracapsular fracture of the femur is an illustration of this kind. It is said, and the saying is supported by a few cases, that if in a case of fracture, it be necessary to tie the principal artery of the limb to restrain hæmorrhage, that the consolidation is interrupted. I have seen a very marked case, in which the same injury which fractured a man's leg injured the lower part of the spine; he lived five weeks, but there had been no effort at reparation. It is rare that osseous union is obtained in the patella and olecranon, but the fibrous medium is such as to admit of the performance of the ordinary functions of the part. Again, in intra-capsular fractures, if of the superior extremity, the neck of the humerus, for in-

stance, the functions of the part are after a time restored; in the neck of the femur, perfect restoration of the function of the part is extremely unfrequent.

Artificial Joints.—Supposing a false articulation to occur, an immoveable apparatus will sometimes bring about union. Walker applied blisters to the part without much success. The actual and potential canterics have been applied by Kirkbride and others. Some persons have cut down upon the bone, and applied, between the ends, various potential caustics, sometimes with success. Mayor once passed between the fragments the canula of a trocar, and left it there eight hours; through this canula, he introduced a stylet, heated to the temperature of boiling water;—the case succeeded. Hunter and others have advised that the fragments should be rubbed against each other to destroy the articulating surface; this rubbing must be violent and often repeated. All these means have been used with occasional success, and all have failed; whether these means, or any of them, should be employed previous to resorting to the painful operation of excision, is with some persons a matter of doubt; but I think it ought not to be. The seton, imagined by Physic, has been a good deal used, and with a fair share of success; his operation has been variously modified. Sommé passes a metallic ligature around the false joint, and tightens it until it passes fairly through it. The seton, occasionally, produces a speedy consolidation, but sometimes it is left in place for many weeks without effect.

In a lecture of Sir P. Crampton's, continued in the Dublin Press for Nov. 20, 1839, he says, in speaking of the seton as a means of curing artificial joint, "My friend and colleague, Mr. Rynd, has lately modified the operation. Instead of passing the seton between the ununited extremities, he merely passes it so close to, and in such a direction, as to be in contact with a considerable portion of their circumference. The inflammatory action thus created seems to be sufficient to set up the ossific process, for in the two cases which he has treated in this manner, the operation has been attended with the most complete success." I have no wish to detract from the merit of Mr. Rynd, but it is my duty to mention that, in Mr. Gulliver's report for 1835, he says, in speaking of the remedies for the cure of "preternatural joints," "they seem to have been exclusively directed to the broken extremities of the bone, a practice which I think is at variance with correct pathology; because that is precisely the situation in which the ossification is last set up, and, therefore, not the place where we might expect to incite the process." "The deposition of bony matter commences at points distant from

the extremities of the fracture: those points are marked *a, a* in the diagram.

It is at these points I would venture to propose, that the attention of surgeons should be directed, in the treatment of artificial joints. If the seton be used, I think there should be two of them placed at a proper distance from the line of fracture." Mr. Rynd's cases are very satisfactory, as confirming the correctness of Mr. Gulliver's views on the subject.

In 1760, White proposed for such cases a new remedy—*resection*; the operation is performed by cutting down upon the false joint, on the side opposite to that upon which the large vessels and nerves are found, and as near as may be where the bone is most superficial; the two extremities are then sawn off; sometimes only one is sawn off, and the other scraped; the parts are then brought together, and carefully maintained in contact until the consolidation is complete. Although the operation not unfrequently fails, yet as the cases of success are much more numerous, the operation fairly takes its place in surgical therapeutics.

It clearly should not be performed, neither should the seton, nor the direct cauterisation, be had recourse to, before other means, such as perfect immobility, blisters, and rubbing the ends, have been fairly tried. In most cases it will be advisable to employ the seton first; it causes less suffering and fewer accidents, and if we fail we can still recur to resection. I know so little of the application of the actual cautery in such cases, that I am not disposed to hazard an opinion upon the subject, further than to remark that in cases of fracture with complications, where a wound is in such a state as to require an energetic modification, the object may be attained by the cautery.

Deformed Union.—One point more remains to be considered: union may be obtained, but with considerable deformity; can this deformity be remedied when the bones are viciously consolidated? Fabricius ab Aquapendente, and Purmann, and at a later period, Osterlen, have maintained, that frequently the callus may be ruptured with success. Osterlen details eight cases in which the limb was restored. He ruptured the callus by pressing upon the projecting part, at the same time that forcible extension and counter-extension are practised. Weinhold proposed a remedy for such cases, by inserting a seton. In the case he detailed the callus was broken down by suppuration at the end of seven weeks, and the case did well.

Wasserfuhr, in such a case, cut down upon and sawed off the angular part; the patient was cured, but after much suffering. Although a certain quantity of success seems to have attended these operations, the dangers to which they expose the patient are so great, that they should not be performed without the sternest necessity.

Having occupied so much time in the consideration of fractures generally, I shall think no apology necessary for glancing slightly at those which are of minor importance. Fracture of the head and spine will be best discussed when we treat of the diseases and injuries of those organs.

NASAL BONES.

A fracture of the nasal bones results from a direct cause, commonly a fall or a blow; it may be simple, or compound; in the former case the diagnosis is not always easy, in the latter it can rarely be difficult. It is merely necessary to apply a finger and thumb upon the fractured part, and to introduce a finger into the nasal fossa, to be at once informed of the condition of the part. The fracture may extend to the lachrymal duct, may cause injury to the Schneiderian membrane. If it extend to the lachrymal apparatus, the internal side of the base of the orbit and the corresponding part of the eyelid will be ecchymosed.

If simple, and there be no concussion of the brain as a consequence of the injury, there is no deformity. If it be compound, there may be a good deal of displacement, and the fragments must be raised by introducing a sound or the finger into the fossa for the purpose. If there be, after reduction, a tendency to further displacement, it may be necessary to introduce a plug of lint into the affected fossa, to maintain it permanently; in that case a piece of elastic catheter may first be inserted, so that there may be no interruption to respiration. Petit thinks plugging unnecessary, but I have known it very useful.

MALAR BONE.

The malar bone and the zygoma are exposed to external violence, and may be fractured by a blow or a fall. A portion of the zygomatic arch may be fairly detached, but this is not usual; if it be, that portion may be dragged down by the masseter. It is not always easy to make out the kind of injury which has been sustained; if there be a depression at the centre of the arch, or if it be carried down by the masseter, the sight and the touch must detect it; if it be driven in towards the orbit, the irregularity of the circumference of that fossa will be obvious.

The reduction of this fracture cannot be made, if there be simple depression and no wound; if there be a wound, we may be able to introduce a lever by which the bone

may be raised. Delpech, in a case of the kind, recommended that an incision should be made for the purpose of using the elevator. If the bone be pushed towards the orbit, we may act upon it at the base of the orbit, or by the mouth.

SUPERIOR MAXILLA.

A large number of cases of fracture of the superior maxilla, caused by direct violence, are on record; a few cases where the shock has been communicated through other bones, the inferior maxilla, for instance. Whether succeeding to violence, directly or indirectly applied, the mobility of the alveolar process, or the roof of the palate, the crepitation of the fragments, and the acute pain felt, if the patient attempt to crush, between the teeth, any hard substance, usually serve to distinguish it; if there be no cerebral injury, it is not usually a dangerous accident, unless there be great contusion.

Once ascertained, we must endeavour to bring the fragments into apposition; sometimes, if the mobility be great, we may keep the part in contact by twisting wire around the teeth; sometimes, however, much difficulty is experienced in keeping them reduced. The patient must not talk, and he must take nothing but liquid food, until all inflammatory action has subsided, and the parts are consolidated. If there be much inflammatory action or cerebral disturbance, it must be energetically treated by antiphlogistic means.

LOWER JAW.

If the lower jaw were less strong and less moveable than it is, it would be very frequently the seat of fracture. Its superficial situation, its large surface, the place which it occupies, and the projection it forms, exposes it to many chances of injury.

There are several points of this bone where fracture may occur; the body of the bone, at a certain distance from the symphysis, is the point most commonly affected. If it occur between the symphysis and the insertion of the masseter, it is called fracture of the chin; between the masseter and the coronoid process, fracture of the angle. At the symphysis itself, it is almost universally admitted, fracture does not occur; still the opinion is incorrect, but the accident unquestionably is very rare. It is rare to see fracture of the branches: the condyle or the coronoid process is sometimes detached; the angle may also be separated, as well as a portion of the alveolar border. The fracture may be single or double; in the latter case, one is usually situated on either side of the symphysis, so that the centre is fairly detached. It may

be broken into many fragments. The direction may be transverse, vertical, or oblique; horizontal, if the neck, the condyle, or the coronoid process, be affected. If the fracture affect the branches, displacement is infrequent; this is owing to the mode of insertion of the masseter and pterygoid muscles. The fractured extremity of the coronoid process is described as drawn up by the temporal muscle, but this cannot happen unless the tendinous fibres of that muscle, which are inserted about its base, be destroyed. As to the body of the bone there is usually little displacement; if there be any, it is vertical, the portion nearest the symphysis being drawn down by the muscles attached to the chin, whilst the other portion is drawn upwards by the temporal masseter and pterygoid muscles. Almost always these fractures are caused by direct injury. They are easily made out: severe pain at the moment of the accident, increased by mastication, are the principal symptoms where there is no displacement. Soon the mucous membrane over the point assumes a violet colour, which extends to some distance, and is a true ecchymosis. If there be displacement, the line of the teeth will be irregular. Although there be no displacement, there is almost always a mobility, which produces crepitation. If we place the thumb along the dental arch near to the supposed fracture, and move the other portion, the displacement is obvious; but this must be cautiously done. At first the quantity of saliva excreted is a great inconvenience, because the mouth is continually filling.

Treatment.—Unless there be much comminution, or the injury be complicated by other lesion, fracture of the lower jaw is not a dangerous accident; and the apprehensions formerly entertained, of injury to the vessels and nerves of the dental canal, are no longer felt, though paralysis of certain muscles of the face has followed this injury. The reduction is usually easy, and the level of the teeth is a good test of its complete accomplishment. To maintain it in this state, it would be sufficient to bring both jaws together, and fix them; but this cannot be long persisted in, and, therefore, other means are necessary. Moistened card-board, or milled board, may be moulded along the inferior arch of the bone, and there maintained by bandages, until it is dry, when it will be found to form a solid cast, exactly corresponding to the ramus, and capable of retaining the fragments immoveable and in contact. Some persons place soap-plaster to prevent the irritation which the board might otherwise occasion. Hippocrates recommended that the tooth on each side of the puncture should be kept together, by winding gold or silver wire

around them. It is unquestionably a useful suggestion; but, though it would be difficult to urge any decided objection against it, it is not often used in the present day. Although in many cases those simple means sufficed, it was found necessary to invent a parabolic curve, to be applied upon the dental arch. Many modes of accomplishing this object have been invented: the common mechanism being, to take as a point of support the base of the jaw, to place a hollow gutter over more or less of the dental arch, and to connect them externally. The inconveniences of these machines, is the necessity of having a foreign body continually in the mouth, and this many patients will not submit to. Of these apparatuses the following, invented by Mr. Lonsdale, seems to answer better than those of Muys, Bertrandi, Boyer, Ruterick, and Hpuzelot.

The grooved plate C, D, E, or F, is fitted on the teeth; the chin-piece, B, is then passed along the vertical rod A, until it presses firmly against the base of the jaw. The lateral plates G, G, are intended to keep the jaw firmly fixed.

During treatment, liquid food alone should be taken; and speaking, or any thing requiring motion of the jaw, should be avoided.

Usually, by the 36th or 40th day, consolidation has taken place; sometimes by the 20th or 25th day. I have a specimen, in which union took place by means of ligamentous matter, constituting, in fact, a false joint; and yet it did not interfere much with mastication. Under ordinary circumstances, the patient should very gradually resort to the use of solid food.

THE

ENTOZOA OF THE HUMAN EYE, AND OF OTHER VERTEBRALIA,

CONSIDERED WITH REFERENCE TO THEIR
NATURAL HISTORY, AND IN A NOSOLOGICAL
POINT OF VIEW:

*The Account being taken chiefly from Von
Ammon's Ophthalmological Journal, and
other Medical Publications.*

BY A. FRANZ, M.D.

NUMEROUS cases have been recorded by early medical writers, in which a species of thread-worm has been met with in the eyes of horses and of horned cattle; whilst in the eyes of other vertebralia, worms, either of this or any other species, have been less frequently observed. A few instances of parasitic animals occurring beneath the conjunctiva of the human eye, have been noticed by ancient authors; but the account they have handed down to us, as well of the animals themselves as of the pathological changes occasioned by their presence, is but very imperfect. Soemmerring published, in the *Isis*, 1830, p. 717, the first well-marked case that has been recorded of cysticercus cellulosæ, which he found in the anterior chamber of the human eye; and since the date of this publication, several similar cases have been met with, which have been well and fully described by those medical men under whose care they came. But it is to Dr. Von Nordmann, of Odessa, that we owe the very important discovery of filaria and of monostoma in the human eye.—(Mikrographische Beiträge zur Naturgeschichte der wirbellosen Thiere, Heft II. Berlin, 1832). To Dr. Geschlecht, of Dresden, we are indebted for the interesting account of distoma, of filaria, and of an echinococcus, which he found in the human eye.—(Von Ammon's Journal, Band iii. p. 74 and 405.) The attention of these two gentlemen was not confined exclusively to the human eye; they examined likewise the eyes of a great number of fishes, amphibia, birds, and mammalia, and their researches have been rewarded by the discovery of a great variety of entozoa, which may be arranged, according to Rudolphi's system, in the following order:—

ORDO PRIMUS. NEMATOIDEA.

Genus I. *Filaria*.

1. *Filaria medinensis*.—One inch and a half in length; about the thickness of a thin violin string; rather thicker at one extremity than at the other; ash-coloured; and having at each extremity numerous little spots. Found under the conjunctiva of the human eye, by Bajon, *Mémoires pour servir à l'Histoire de Cayenne et de Guiane Française*, &c. Paris, 1777-78, an extract of which is inserted in *Journal de Med.* vol. xlix. p. 386 (1778); by Mongin, *Journal de Med. de Paris*, 1770, t. xxxii. p. 338; by Larrey, *Mémoires de Chirurgie Militaire*, vol. i. p. 51; and by Gaertner, *Schoen's Handbuch der Pathol. Anat. des Menschlichen Auges*, p. 226.

2. *Filaria lacrymalis*.—Very thin, and diminishing in size towards each extremity; the mouth is narrow. The male is 5 to 6 lines in length; from its posterior extremity projects the penis, situated a little anterior to which is the anus. The female is 7 or 8 lines in length, having the anus at the posterior extremity, and the organs of generation at the anterior part of the body. In the excretory ducts of the lachrymal gland of horses and horned cattle, and occasionally between the eyelids and the globe.—Rhodes, *Journal de Physique*, Mars 1810, p. 214; *Dictionnaire des Sciences Naturelles*, t. liii. p. 440. Gurlt, *Lehrbuch der Pathol. Anat. der Haus-und Säugethiere*, Berlin 1831, p. 347.

Filaria abbreviata.—The female is 8 lines in length, whilst the male is only from 6 to 7 lines. The body is very thick in proportion to its length, becoming gradually pointed towards its extremities, the posterior of which is spiral in the male, and in the female straight. The head is thin and obtuse; the mouth circular, the penis filiform, oviduct very wide. Found by Bremser in the neighbourhood of the eye of the *Motacilla staphylina*, and under the *membrana nictitans* of the *Falco naevius*, and described by Rudolphi, *Entozoorum Synopsis*, Berol. 1819, p. 210 and p. 337.

4. *Filaria oculi humani*.—Varying in length, from $\frac{3}{4}$ of a line to $5\frac{1}{2}$ lines; very thin and delicate, perfectly filiform, and generally met with in a convoluted state. The head is pointed, the posterior extremity of the body rather obtuse, and

armed with a short, thin, and curved spine; the anus somewhat thickened around its margin. In the human crystalline lens.—Von Nordmann, *opus cit.* Gescheidt, *loco cit.*

5. *Filaria bonasiae*.—Length from 5 to 6 lines; of a white colour, and, when taken alive from the eye, its movements observed to be serpentine. Found in the vitreous body of the woodcock, by Von Nordmann, *o. c.*

6. *Filaria crassiuscula*.—Four and a half lines long, and one-sixth of a line thick throughout nearly its whole extent. The head is round, and presents two small round papillæ, one at each side; the mouth is elliptical. The posterior extremity is of a conical form, and a little before it is situated the anus, which is somewhat thickened around the margin. Found alive in the aqueous humour of the anterior chamber of *Gadus aeglefinus*, by Von Nordmann, *o. c.*

7. *Filaria armata*.—Colour white; length, $3\frac{1}{2}$ lines; diameter about one-sixth of a line in its whole extent, with the exception of the posterior extremity, which is a little broader, of a very obtuse and rather flat form, and from which a short obtuse spine projects. The head is round, and furnished with four papillæ, each of which presents in its centre a small impression. The mouth is small and circular. Met with in the vitreous body of the *Falco lagopus*, by Gescheidt, *l. c.*

8. *Filaria oculi canini*.—Colour white; length 4 lines; rather thick in proportion to its length; of uniform diameter nearly throughout, decreasing a little towards the posterior extremity only, which is of a conical form. The mouth is circular, and furnished with three small round papillæ. In the vitreous body of the dog. Gescheidt, *l. c.*

9. *Filaria papillosa*.—Colour whitish; from one to three inches in length; of the diameter of a common sewing-thread, decreasing towards the posterior extremity, which is slightly curved. The body is elastic. The head rather large, rounded, and having a group of little spots. The mouth circular. In the anterior chamber, and between the membranes of the eye of horses and horned cattle.—Hopkinson, *Transactions of the American Philos. Society*, 1786, vol. ii. p. 183; Morgan, *ib.* p. 383; Michaelis, *Med. Pract. Bibliothek*, vol. i. 1785, Anhang, p. 243; Will, *Tenffel's Magazin für Thierheilkunde*, vol. i.

Karlsruhe, 1813, p. 287; Sick, *Jahrbücher k. k. Oester. Staaten*. vol. ii. Wien, 1813, p. 174; Greve, *Erfahrungen und Beobachtungen ueber die Krankheiten der Hausthiere*, vol. i. Oldenburg, 1818, p. 173; Anderson, *Edinb. Med. and Surg. Journal*, 1805, vol. ii. p. 306; Deguillême, *Gohier Mémoires*, tom. ii. p. 435; Kennedy, *Trans. of the Royal Soc. of Edinb.* vol. ix. p. 167; Boudgourd, *Bulletin des Sciences Med.* tom. vii. p. 120; Twining, *Veterinarian for 1828*, vol. i. p. 114; Percival, *ib.* p. 74; Chaignaud, *ib.* p. 77; Desmarest, *ib.* p. 79; Gibb, *ib.* p. 194; Molyneux, *ib.* p. 309; Leuckart, *Versuch einer naturgemaessen Eintheilung der Helminthen*, 1827, p. 29; Gurli, *Lehrbuch der Pathologischen Anatomie der Hausaeugethiere*, vol. i. 1831, p. 341; Skeavington, *Veterinarian for 1824*, vol. vii. p. 196.

Genus II. *Oxyuris*.

1. *Oxyuris velocissima*.—Length one-tenth of a line, thickness in proportion to its length, as 1 to 40. The body diminishes in size towards the posterior extremity, and terminates in a long and very fine spine, at some distance before which is situated the anus. The head is obtuse, and entirely unarmed; the mouth circular. Movements of the animal exceedingly quick. In the aqueous and vitreous humour of the eye of the perch. Von Nordmann, *o. c.*, and Gescheidt, *l. c.*

Genus III. *Ascaris*.

1. *Ascaris oculi ranæ*.—One-fourth of a line in length. At the anterior extremity, the animal is large in proportion to its length, and diminishes in size towards the posterior. The head is slender, and rather pointed. Movements very quick. The colour light. In the vitreous body of the common frog. Von Nordmann, *o. c.*

ORDO SECUNDUS. TREMATODA.

Genus I. *Monostoma*.

1. *Monostoma lentis*.—Length of the animal one-tenth of a line; its movements rather slow. In the lens of the human eye.—Von Nordmann, *o. c.*

Genus II. *Distoma*.

1. *Distoma lucipetum*.—The animal is flat, from 2 to $3\frac{1}{2}$ lines in length, and about half a line in breadth; of a white

colour, but assumes a somewhat reddish tint in the vicinity of the suckers, which are situated at the abdomen. The posterior sucker is twice the size of the anterior. The portion of the body between the suckers is the smallest; the greatest breadth is at the suckers; it decreases, however, in size towards its posterior extremity. Beneath the membrana nictitans of *Larus glaucus* and *fuscus*.—Bremser and Rudolphi, *o. c.* p. 367.

2. *Distoma annuligerum*.—This animal is enveloped in an oval cyst, which is one-quarter of a line in length, of a white or yellowish colour, but perfectly opaque. The figure of the worm is either spindle-shaped, circular, or cruciform, apparently dependent on the contraction and expansion of its different parts. The mouth and the sucker, situated in the centre of the body, are equal in size. The intestinal canal is bifurcated. Six or seven animals of this species are generally present at the same time. In the vitreous body of *Perca fluviatilis*.—Von Nordmann, *o. c.* Gescheidt, *l. c.*

3. *Distoma oculi humani*.—This animal also is enveloped in a white and delicate cyst; its length is from one-quarter to one-half of a line; its shape varies, like the former, in contraction and expansion. In the latter state, it assumes the form of a lancet, its breadth being in proportion to its length as one to three. The anterior sucker presents a simular appearance, and is the smallest. The intestine is bifurcated. Gescheidt found four of these animals in the crystalline lens of one individual. *l. c.*

Genus III. *Diplostomum*.

This genus is found in the vitreous and aqueous humour, in the Morgagnian fluid, and in the substance of the lens, in the eye of the perch, carp, and other fishes, by Von Nordmann, *o. c.*, and Gescheidt, *l. c.* A very large number (from 50 to 300) of these parasites are generally met with in the same eye: they move slowly, but in various ways; the body is of a whitish colour, and transparent. They are exceedingly minute, about one-sixth of a line in length, and a great many different species are discernible (Von Nordmann, 58), which may be well arranged according to their characteristics, under the two following heads:—*Diplostomum volvens*, and *Diplostomum clavatum*.

1. *Diplostomum volvens*.—The body

flat, more or less oval, and furnished at its anterior margin with two auricular processes, which are capable of being retracted; the mouth rather wide, and circular. The abdomen presents two suckers, the posterior of which is always the largest. The posterior extremity of the body is somewhat thickened at its terminal margin, is more or less curved downwards, and has on its superior surface a kind of pouch. The intestine is bifurcated.

2. *Diplostomum clavatum*.—The body is rounded, and of a conical form, the anterior portion being of the largest diameter, and obtuse; the terminal margin of its posterior extremity is not thickened. A number of fine incisions are seen around the whole body. In all other particulars it resembles the former species.

Genus IV. *Holostomum*.

1. *Holostomum cuticola*.—This animal is of a milk-white colour, is enveloped in a white cyst, and lies generally in a curved form. It is half a line in length; the body consists of two portions, each of which is of an oval form, rather thick, convex on the dorsal, and concave on the abdominal surface. The posterior portion is about one-third smaller than the anterior, which presents near the centre of the abdomen a rudiment of a sucker. The mouth is merely a small slit, and is retractile. The intestine is bifurcated. In the conjunctiva, cornea, and iris of the carp.—Von Nordmann, *o. c.*, and Gescheidt, *l. c.*

2. *Holostomum brevicaudatum*.—This species is one-third of a line in length, and very much resembles the former, except that its anterior portion is cordiform, and the posterior two-thirds smaller and three-fourths shorter than the anterior, and somewhat flattened. In the vitreous body of the perch.—Von Nordmann, *o. c.*

ORDO TERTIUS. CYSTICA.

Genus I. *Cysticercus*.

1. *Cysticercus cellulosæ*.—This hydatid attains, occasionally, the size of a small pea, but is not usually so large. The body consists of a globular vesicle, which sometimes changes its form, and becomes oval or oblong. The neck is slender, the head slightly enlarged, and presents a double circle of hooks, around which are situated four prominent suckers. This animal possesses the power of extending its head and neck beyond

the vesicle, and of retracting them again within it. Found in the anterior chamber of the human eye by Soemmering, *l. c.* A similar case has been met with by Logan, which he published in a pamphlet: "Case of Animalcule in the Eye of a Child, 1833." This case was examined also by Mackenzie, LONDON MEDICAL GAZETTE, vol. xii., p. 110. Another case of this kind has been met with by Neumann, Rust's Magazine, vol. xxxiii. p. 59. Estlin found the same animal twice beneath the conjunctiva of the human eye.—LONDON MED. GAZ., August 25, 1838, vol. xxii. p. 830; *ibid.* March 27, 1840, p. 35. It has been met with in the same situation by Hoering, Med. Correspondenz. Blatt, vol. ix., No. 25, p. 196; and also by Baum, Berliner Medical Zeitung, 1832, No. 16. Mackenzie found six or eight worms of this species in the cellular substance of the upper eyelid in the human subject.—Treatise on the Diseases of the Eye. Third edit. p. 909. The same animal has been met with in the pig, under the eyelids, by Greve—Krankheiten der Hausthiere, Oldenb. 1821. vol. ii. p. 79; in the chambers of the eye, in the vitreous body, and in the neighbourhood of the eyeball, by Von Nordmann, *o. c.*; in the anterior chamber, and between the choroid and retina, by Gescheidt, *l. c.*

Genus II. *Echinococcus*.

1. *Echinococcus hominis*.—This hydatid consists of a pretty large vesicle, composed of a firm white membrane, containing another vesicle within it, which is somewhat smaller, of a blueish-white colour, and of a very delicate texture; the space between the two vesicles being filled by an aqueous fluid. The inner vesicle, which is likewise filled by a serous fluid, incloses a great number of very minute worms, of a round or oval form, either floating in the fluid, or adherent to the inner surface of the vesicle. In several of these animals the suckers were plainly observed, when placed under the microscope, but the circle of hooks could not be distinguished. Found between the retina and choroid of the human eye, by Gescheidt, *l. c.*

Hydatids, of various forms and sizes, have been met with by different medical men; but the account which they have given of these animals is not sufficient to enable us to determine their species. From what has been stated, however,

respecting them, it is probable they belong to the genus *Echinococcus*. Schmidt (Ueber die Krankheiten der Thraenenorgane, Wien, 1803, p. 73, and in Himly's Ophthalm. Bibliothek, vol. iii. p. 159.) gives an account of a large hydatid which he discovered in the lachrymal gland. Beer (Lehre von den Augenkrankheiten, Wien, vol. ii. p. 589, note) mentions an instance in which he found a large cyst in the neighbourhood of the lachrymal gland. Lawrence met with a case of cyst in the orbit, containing hydatids (Medico-Chirurgical Trans. of London, 1832, vol. xvii. p. 58). Delpsch found a large hydatid in the orbit behind the lachrymal gland (Chirurgie Clinique, vol. i. p. 99). Rossi (Memorie della reale Accademia delle Scienze di Torino, 1830, t. xxxiv. p. 636.) states that he has met with small hydatids in the choroid and retina.

Having thus given a brief description of the various species of Entozoa found in the eye, so far as they have hitherto been examined, it remains now to offer a few remarks on the causes which produce these parasitic animals, and on the pathological changes observed in the eye when worms are present.

As *remote causes*, climate, and the entire habit or manner of living, may be regarded as the two principal. In India, for instance, horses which are kept in narrow vallies or damp countries, and according to Skeavington's statement, those which have foul or marshy water, and bad or wet grass, for their food and drink, are subject to worms; whilst in Europe, under similar circumstances, the occurrence is very rare. Fishes, as is observed by Von Nordmann and Gescheidt, living in mountain streams with a sandy or gravelly bottom, are rarely, if ever, subject to worms in the eye; whilst in the eye of those that inhabit ponds or rivers with a marshy or clayey bottom, these parasites are almost always generated, which is especially observed in the eyes of old fishes.

As the *proximate cause* of the production of worms in the eye, must be assumed an abnormal state of nutrition in that organ, dependent on some morbid action, such as diminished absorption, excessive secretion, stagnation, &c.; and a certain alteration in the quality of the lymph or mucus, &c., which, in a healthy state, and under a regular action, would appropriately serve the ends of nutrition and reproduction, but being

thus prevented from doing so, gives rise to parasitic creations in the eye. These parasites, when once produced, are not only capable of keeping up that morbid state by which they are generated, but also of producing pathological alterations in the different parts of which the eye is composed. These pathological alterations, occasioned by the presence of worms as foreign bodies in the eye, which, previously to the formation of the parasites, was already diseased, present themselves under different forms, dependent partly on the susceptibility of injury possessed by the animal in whose eye they may happen to be lodged, and partly on the seat of the worm itself, and on its particular species.

In the lachrymal gland, and in the neighbourhood of the eye-ball, within the orbit, cysticercus and hydatids have been met with. In general, the complaint came on slowly, and was attended with inflammation, severe pain, swelling of the lids, and tumors, by which the eye-ball was protruded from the socket. In some cases the structure of the globe was not injured; but the iris became motionless, vision was lost, and the general health much impaired. In those instances which admitted a timely removal of the parasites from the tumor, by an opening made into its most prominent part, the cyst, where they had been lodged, having been well cleared out, was obliterated by subsequent inflammation and suppuration; the eye was retracted to its proper place, the sight returned, and all other symptoms entirely disappeared. But in those cases where this could not be accomplished, the structure of the globe being already injured, and the complaint altogether too far advanced, the eye and lachrymal gland were extirpated, in order to save the life of the patient. The small cysticercus met with in the neighbourhood of the eye-ball, within the orbit, in the pig, has been found to occasion chronic inflammation, from the pressure of the worms upon the parts surrounding them, which was followed by its usual sequelæ. One pig, beneath the eye-lids of which cysticerci were found, was incapable of closing the lids, and at last could not move them at all. The filariæ found in the excretory ducts of the lachrymal gland of horses and horned cattle, as also under the membrana nictitans of birds, produced by their quick movements inflammation and profuse secretion of tears.

Under the conjunctiva, covering the globe, filaria and cysticercus have been met with in the human eye; the latter also in the pig. The former occasioned the most vehement pain, although scarcely any sign of inflammation was present. In one case, the worm disappeared from beneath the conjunctiva, and exhibited itself again under the external covering of the upper lid, resembling a small subcutaneous vein, moving in all directions. An opening was made, and the worm extracted. The cysticercus occasioned a small tumor of the conjunctiva, which was a little reddened; but no actual pain, merely a slight pressure was felt. The tumor was opened, and the worm taken out. The conjunctiva covering the tumor was a little thickened; but the small puncture made for the removal of the worm soon closed, and no trace of it remained. The portion of the conjunctiva, where a cysticercus had been lodged in the eye of a pig, presented increased thickness and vascularity, and the cornea a slight opacity.

In the substance of the proper membranes of the eye-ball, worms are rarely seen. The holostomum has been met with in the cornea and iris of fishes only. The situation of the animal was marked by round dark spots, apparently consisting of altered cellular tissue, with dark pigment enclosing the cyst, in which the worm generally lies in a convoluted state. No signs of inflammation or vascularity were present. In one case, however, the cornea was partly destroyed, by the presence of three animals of this species.

In the anterior chamber of the eye, in man and in the pig, cysticercus has been found; filaria in that of horses and horned cattle; and diplostomum and holostomum in that of fishes. The formation of the cysticercus in the human eye was preceded by repeated attacks of inflammation; but, during the existence of the animal in that organ, neither inflammation nor pain was present. In one instance, however, inflammatory symptoms exhibited themselves some time after the worm had been generated; but, on the removal of the animal, by an incision in the cornea, the eye regained its healthy condition. In another case, which occurred in a boy, 14 years of age, of very scrofulous habit, the worm slipped into the pupil, and, whilst remaining in this situation, caused very severe pain. A strong infusion of belladonna was applied

to expand the pupil, so as to release the animal; but this proving of no avail, the animal, which in this instance was mistaken for the lens, was removed from the pupil by couching it with a needle passed through the cornea; but, on the third day after this operation, a severe ophthalmia came on, and the eye suppurated. In the pig, in which the same worm was found, a portion of the cornea was rendered opaque, and the ligamentum ciliare reddened and thickened. Filaria, when found in the eye of horses, always occasions acute inflammation, which spreads from the conjunctiva over the sclerotica and cornea, proceeding frequently to a fearful extent, and is often followed by suppuration, and rupture of the eye-ball; but if the worm die, or is extracted before the inflammation has made much progress, the eye may resume its healthy condition. In the eyes of cattle, the same results are observed, but the disease does not proceed so rapidly. The severity of the disease, caused by filaria, seems most probably to depend upon the quickness of the animal's movements, and on its sometimes making its way out of the anterior chamber into the cellular tissue, interposed between the different membranes of the eye; and the more rapid progress of the disease in horses than in cattle, appears to be dependent on the former being more susceptible of inflammation than the latter. The diplostomum and holostomum, found in the anterior chamber of the eye in fishes, produce scarcely any marked signs of disturbance or pathological alteration; the aqueous humour is sometimes merely rendered slightly turbid.

The appearance of those crystalline lenses and capsules, in which parasitics have been found, leaves no doubt that the natural function of these parts has been disturbed long before the formation of the worms, whilst the worms, after their production, have kept up and increased that morbid action by which they were generated. The lens and capsule of the human eye, between which distomata were found, presented only a slight opacity, which was, however, greatly increased in the immediate vicinity of the worms; in this part the lens and capsule were both altered in texture also. Other human lenses and capsules, which were affected with filariae, presented nearly the same appearance; but the lens itself was very soft, and its fibres seemed more strongly developed, and their proper and

regular arrangement considerably disturbed. The lens and capsule of the eye of fishes, which is so often the seat of trematoda, were found less opaque; but the Morgagnian fluid, where they are generally met with, was always more turbid. In those cases where the lenticular capsule was affected, its posterior part only was observed to be opaque.

In the vitreous body, the cysticercus has been found in the eye of the pig; diplostomum and holostomum in that of fishes; and filaria in that of the dog, the horse, and the Falco lagopus. The filaria appears not to have been generated in the vitreous body, but to have made its way out of the anterior chamber into it, and in this situation has occasioned great injury to the eye. In the other cases, where the above-mentioned parasites have been found in the vitreous body, it was more or less turbid, or quite opaque, and in the immediate vicinity of the worms appeared almost white, resembling effused lymph. In one case coagulated blood was found in the vitreous body. The hyaloid membrane, especially in the neighbourhood of the worm, was thickened, very soft, and sometimes changed into a brownish mass.

Injuries caused by worms lodged between the retina and choroid, or between this membrane and the sclerotic, are of the utmost interest, and vary according to the different species of worms. Nematodea and trematoda, by the rapidity of their movements, occasion severe acute inflammation; while the cystica, growing slowly, and being more confined in their movements, cause nearly the same alterations as are produced by an accumulation of fluid between these membranes. In the human eye, where an echinococcus was found between the retina and choroid, the vitreous humour had almost entirely disappeared, and the retina, which was rather thickened, was so intimately united with the remainder of the vitreous body, that it formed but one membranous mass of a bluish and reddish colour, running in a somewhat cylindrical form, from the entrance of the nerve at the posterior hemisphere of the globe, in the direction of the axis of the eye, towards the anterior hemisphere, where it united with the lens and cornea ciliaris. The space thus left between this cylindrical and membranous body and the choroid, which remained in its proper situation, was filled up by the echinococcus. The choroid was thinner

than usual, of a varicose vascularity, and deprived of its colouring pigment. The small cysticerci found between the choroid and retina, and between the latter membrane and the hyaloid, in the human eye, occasioned more or less functional derangement; the organic alterations were observed to be but slight in these cases. The cysticerci met with between the retina and choroid in the pig, were surrounded by a lymphatic exudation, on the surface of which, as well as in the retina, a fine vascularity was observed. In one case, where six cysticerci, together with some coagulated blood, were found at the same time in the vitreous body, an ossification of pretty large extent, and three and a half lines in thickness, was discovered at the inner surface of the sclerotic, surrounding the optic nerve at its entrance. This ossification proved to be hollow, and the abode of six other worms of this species. The whole posterior hemisphere of the sclerotic was observed to be much thicker than usual; the choroid and retina were not altered. In the eye of fishes, where diplostomum and holostomum are sometimes lodged between these membranes, an alteration of texture is usually seen surrounding the worm, and resembling effused lymph, tinged with the pigment of the eye.

In concluding this brief account of the entozoa discovered in the eye, it may be not uninteresting to remark, that the same species of worm found in the eyes of horses and cattle, have, at the same time, been met with in the thorax, abdominal viscera, scrotum, spinal cord, cellular substance, nay, even in the mesenteric veins, and celiac artery, of the same animal. In the pig, where cysticerci were found in the eye, worms were, on examination, discovered also in other parts of the animal, and especially in the brain.

Golden Square, April 23, 1840.

CURE OF SQUINTING.

To the Editor of the Medical Gazette.

SIR,

By desire of my friend, Dr. Franz, I beg to forward you the further report of the two cases of strabismus, operated upon by him, the account of which appeared in your journal on 17th April last, as also

of another case, operated upon since.—I remain, sir,

Your obedient servant,

F. STEINHAUSEN, M.R.C.S.

Upper Terrace, Islington,
May 13, 1840.

A few days after the operation, the conjunctiva presented an increased vascularity at the inner angle of the eye, and slight thickening in its texture near the edges of the wound. The motions of the eye-ball were free in all directions; they caused, however, a slight degree of pain in the situation of the divided muscle, subsiding when the organ was at rest. No sign of inversion could be detected in the eye operated upon. Both in moving the eyes, and in fixing them upon an object, the optic axes corresponded with each other. During the first week after the operation, the patients were permitted to make only a limited use of the eye; but during the second week they began to follow their ordinary occupations. A few days ago, when I again saw these patients, there still remained a slight redness of the conjunctiva at the inner angle of the eye, but the wound had perfectly healed. Both the eyes moved freely and harmoniously, the pupil occupying a proper position. The general health of the patients was good; and, with the exception of aperient draughts, no medicines were required.

Since then, Dr. Franz again operated, in my presence, on another case, of which the following is the account:—

Thomas William Gest, aged 11 years, a boy of strumous habit, with large dark eyes. According to the mother's account, the squinting had first made its appearance in his fifth year, after a severe attack of inflammation which he suffered, in his left eye. On examination, the right eye was found to be perfectly straight, but the left eye to be turned a little upwards, and considerably inwards, so that one-fourth of the cornea was hidden by the inner canthus. On closing the sound eye, he could, with some exertion, move the affected eye outwards a little beyond the orbital axis, but it soon returned to its usual inverted position. He could only read large print. The vessels of the conjunctiva were dilated, resulting from the prior inflammation. He desired the operation, in order to be able to learn the business of a compositor. The operation was performed on the 6th, in the same manner as on the

former patients. The instruments employed were, two wire retractors for fixing the lids; a small scalpel; the curved scissors, for the division of the muscle; and, for fixing the eye-ball, a hook, with the improvement of a sliding-guard, to cover its sharp point, when passed through the conjunctiva. The muscle in this case was remarkably developed, and very broadly attached to the sclerótica. The hæmorrhage, although more considerable than in the former cases, was not of sufficient extent to interfere with the progress of the operation. On removing the hook from the conjunctiva after the division of the muscle, the eye was directed a little outwards, and its motions were free, except internally. Cold water dressings, and an opening draught, were ordered.

On the 7th, the conjunctiva presented an increased vascularity, and the boy complained of a slight pain in moving the organ. The pupil now occupied a proper position. The motions of the eye were free, and both organs acted in unison.

On the 12th, the wound had nearly healed. A slight redness yet remained at the inner angle of the eye, which was now free from pain. The health of the patient continued undisturbed, and no trace of squinting could be detected.

The final result of these, as also of some other cases, Dr. Franz will report in a future number of the *MEDICAL GAZETTE*.

BITE OF A VIPER.

To the Editor of the Medical Gazette.

SIR,

IF you should consider the accompanying case, with one or two observations, as worthy of a place in the columns of the *MEDICAL GAZETTE*, I shall feel obliged by its early insertion.

I am, sir,

Your obedient servant,

HARVEY K. OWEN, M.R.C.S.

Maidstone, April 26th, 1840.

John Burr, æt. 20, of moderate muscular make, when first seen was suffering from a state of collapse, and gave the following history of himself:—That he was a labouring man of good health and steady habits, neither having suffered of late from any illness, or inclined to be

easily frightened; that half an hour previously, while on the road to Maidstone, and gathering some broom, he noticed something moving in the under-wood, which proved to be a viper. On endeavouring to catch it, it became enraged, and flew at his hand. He immediately felt a prick, as of a needle, and, on looking at the part, found that one or two drops of blood had issued from some punctures at the back part of the right index finger. The reptile, on giving the wound, fell off directly, but attempted a second time to reach the hand, in which attempt the man thinks it failed. This feeling of a prick was immediately followed by intense pain in the wounded part, in a short time extending along the forearm to the middle of elbow, and thence to axilla. He describes this pain as being of a burning character, and almost directly followed by great swelling of the hand and wrist: as the pain extended, its severity, in the wounded part itself, somewhat diminished. Simultaneously with its reaching axilla, a pain or feeling of constriction was experienced about the head, throat, and right side of tongue, accompanied also with a sense of heat about these parts. He also complained of having had great difficulty in attempting deglutition. To these symptoms were added nausea (no actual vomiting), dyspnœa, faintness, and a sudden attack of severe pain at *scrob. cordis*, with considerable thirst. It appears that, after being bitten, he was able to catch the reptile, which having destroyed, he took a portion of the fat and applied to the wound on the finger, but, as may be supposed, without experiencing relief. He then hastened on towards Maidstone, and, on presenting himself, his condition was as follows—half an hour, as far as he could guess, having scarcely elapsed since the reception of the injury:—

Countenance pallid, extremely anxious, and covered with drops of perspiration; hands, feet, as well as body, pretty natural as to temperature; pulse small, nearly 100, no irregularity. On looking at the seat of the wound, merely two black specks are to be seen; there is, however, great swelling and tension of the part, having an œdematous appearance, which extends to a considerable distance beyond wrist: great pain, although less severe than at first, extends from the punctures along the anterior part of forearm to axilla. But very

moderate pressure can be borne along this track; pressure over the four or five ribs of the right side also causes pain; an extreme degree of pain at epigastrium, the least pressure there causing him great suffering; no swelling of the right side of face; the tongue, however, has a swollen appearance; it can be protruded but slowly, and in a small degree, and is evidently directed to the side affected. The voice hesitating and thick, and somewhat resembling that of a man suffering from slight intoxication, but, otherwise, he is certainly quite collected and rational: there is also a troublesome thirst and craving for cold drinks, nausea, and slight attempts at vomiting, which appear to aggravate the suffering. A ligature was placed pretty tightly about the wrist; free incisions were also made about the wound, which the patient was desired to suck; very little blood, however, escaped. An emetic of mustard was also given; just previously to taking which, a small quantity of half digested food was brought up from the stomach. The mustard draught was kept down for about half an hour, at which time it operated pretty violently, when the pulse rose in power, his voice became more clear, and altogether he felt improved. A slight return of collapse took place a few minutes afterwards; but, on the administration of the *ip. ammon. co.*, he gradually improved, and was enabled, with assistance, to walk as far as the West Kent Infirmary, and was placed under the care of Mr. Wedd, the senior surgeon of the Institution. On reaching it, at first he felt himself much improved; but, being somewhat exhausted, he was obliged to lie down for some little time, and he had, at this period, two convulsive twitches of the right side. Having been placed in bed, an elliptical portion, including the marks of the bite, was excised from the finger, which was followed up by the application of a large poultice to the hand. To relieve the distressing sensations at stomach, a sinapism was applied, and ammonia directed to be given as required. On leaving him, after about half an hour, his appearance was improved; he had less anxiety, the other symptoms were mitigated, and he had passed about half a pint of clear light-coloured urine. It was found, when the hand was examined about two hours after, that a good deal of blood had

escaped from the incision, and a strip or two of plaister was placed around the finger to exert slight pressure on the artery.

Quarter to 10, P.M. — Improved ; face calm ; pain diminished, but a great deal of soreness ; the epigastric pain was much diminished by the action of the sinapism ; the hand and arm are more swollen ; pulse 90, full, and rather jerking, diminished by moderate pressure ; tongue is protruded easily, and is directed straight forward.

19th April, 10 A.M. — Has passed a pretty good night ; soreness remains along the course of the former pain ; countenance calm ; tongue a little white and dry ; skin rather hot ; pulse 90, as yesterday ; slight thirst. The parts about the wound are more swollen than yesterday, and very tense, extending above the elbow. Ligature was removed, and, bowels not having been relieved since admission, the following powder was given :—

R Hydr. chlor. gr. vj. ; pulv. jalap co. gr. xvj. statim ; mist. salin. ʒiiss. 4tis horis.

9 P.M. — The powder has operated three times pretty briskly, and the man appears much improved ; can bear epigastric pressure without causing pain, as also in axilla ; this last region, up to to-day, was very tender ; tongue a little white ; pulse as before.

20th. — Has not passed a very good night, having had occasional pain about hand and arm ; this has not occurred lately ; very slight general indisposition remains ; arm to-day much less swollen, and wound looks pretty healthy.

Rep. medic. &c.

21st. — Altogether improved ; bowels twice open this morning ; arm diminishing in size ; slight œdematous swelling of hand remaining ; a slight discharge of thin serous matter from wound.

23d. — Continuing to improve, he left the infirmary this morning ; all general uneasiness left him ; the wound still produces a thin serous discharge ; nor is there any attempt at granulation. Since the above date a slight slough has separated, and, at times, there has been slight pain ; but to-day, the 26th, the sore is covered with healthy discharge, and presents a good granulating surface, requiring merely the approximation of its sides by adhesive plaister for its cure.

The accompanying case, although probably by no means rare, affords a good example of the constitutional derangement following the bite of our common viper ; perhaps the only one of British reptiles whose wound is looked forward to with any degree of apprehension : for although we hear of deleterious effects following the stings of wasps and one or two other insects, yet for such result it would appear that either a peculiar delicacy of constitution, or some other peculiarity in the circumstances, is necessary : and again, the effects of these injuries are very different from the one now considered ; for while symptoms of the former take some time to develop themselves, those of the latter are almost instantaneous. The former are regarded with uneasiness as producing a state of excitement or inflammatory action, while the bite of the reptile is directly opposed to the above, appearing to act from the first as a direct sedative, increase of action merely following at a distant period. It has been supposed (an opinion supported by Fontana,) that the immediate effects are chiefly the result of fear in the injured individual ; and, to strengthen this opinion, he states that he has known a person bit without perceiving it, but who, after seeing the blood, and observing a viper near him, suddenly fainted away. In the above case, the wound occurred in a man neither lowered by ill health, or belonging to what is termed, in vulgar parlance, a *nervous* temperament, but whose health had been uninterrupted ; and, at the same time, we may suppose that, being some distance from any place where relief could be obtained, there must have been considerable effort made, on his part, to withstand the approaches of the attack.

As regards the history of the case itself, there is probably nothing novel in it—an acute pain in the wounded part, extending up the arm, (and *en passant* it may be observed that the course of the median nerve was pointed to as its seat). On reaching axilla, this was followed by a sympathy of the whole nervous system, as instanced in the faintness and general malaise, but more especially of the respiratory nerves, the deglutition, respiration, and cardiac action, being almost simultaneously affected, producing a degree of collapse which, at first sight, was somewhat alarming ; for although in these cases a fatal result is

rarely met with, yet such are on record. Fontana mentions one; and Mr. Phillips, in a late number of the *MEDICAL GAZETTE*, relates another. The same surgeon also quotes a case from the *Annales du Cercle Medicaire*, of a woman who, sitting down upon a viper, was wounded in the thigh, and, an hour having elapsed before assistance could be obtained, death followed in thirty-six hours; notwithstanding the internal use of ammonia and the other means were had recourse to. Then again there must be a great increase of danger if occurring in a man suffering from previous disease, more especially of the lungs or heart. In most of the cases on record, and one especially marked in the present, was an extremely distressing pain at the epigastric region—a pain which we probably may regard as of a perfectly neuralgic character, (a term, as a distinguishing mark, objectionable, as we cannot understand pain independent of the nerves,) its sudden approach and equally sudden subsidence being opposed to the idea of its being at all inflammatory; indeed, I think it by no means determined where it is even situated, whether about the stomach itself, being the result of a peculiar action on pneumogastrie, or whether it is more superficially, from the very slight degree of pressure which causes the distress and shrinking of the patient. I am rather inclined to the latter opinion.

As to the treatment, the first application was the fat of the viper itself; for the patient, having killed it, took a little of the fat and rubbed his finger with it: this savours somewhat of the *similia similibus* remedies; it is one, however, in great repute among the uneducated rustics. In regard to the ligature above the wounded part, which has the high authority of Sir Everard Home and Fontana in its favour, it would be a point of great interest to know at what time it ceases to be useful; whether we are to regard the progress of the poison simultaneous with the pain and swelling, or to regard its absorption as being more gradual and protracted; for while, in the first case, a ligature, unless applied immediately, would prove of little or doubtful utility, in the last, which is most probably the case, its application, even after some short time had elapsed, might prove of the greatest importance, and, as a doubt does exist on the subject, it is worthy of a trial in

most cases, being easily applied, devoid of injurious effects, and tending to raise the confidence of the patient. As to the free excision of the part, as prescribed by Mr. Wedd, this, if performed pretty early, cannot fail to be of service, tending to remove altogether the source of the poisoned stream, and thereby a further impregnation. The application of cupping glasses was not, for a very obvious reason, resorted to in this case; for although no doubt can exist, from the experiments of Sir David Barry, of their great utility, yet it must be owned, their application, if not altogether impossible, would be very awkward over one of the digital phalanges, a part, perhaps, more exposed than any other to injuries of this nature. An effort was made, on the part of the patient, to supply this deficiency by suction—a very feeble and inefficient means as compared with the action of a cupping glass, rarification of air being much less capable of being obtained, and the same degree of pressure on the surrounding parts being entirely wanting. In regard to the placing of glasses over a part previously scarified, as recommended by some, I would wish to call to remembrance the following statement of Sir David Barry, that on placing a glass, the air of which has been rarified or partially withdrawn, over a wounded surface, the point which opposes the least resistance to the exit of blood, or of the deleterious matter, is the wound itself; that on scarifications being made, such ceases to be the case, and the more numerous the incisions the less likely is it to take place; and if these extend beyond the area of the vacuum, the contents of the vessels thus divided will cease to be influenced by it, and, therefore, whatever portion of poison has passed beyond the point of division will be carried to the heart just as if no vacuum had been formed. The application of caustics, though as useful as collateral measures, would not appear to be worthy of greater confidence, as being on the whole uncertain in their action; the potassa fusa would probably be most beneficial, as being more searching in its action than the nitrate of silver. The state of deficient circulation remaining after the evacuation of the stomach, will suggest the use of ammonia and the like class of remedies. One form of ammonia, the eau de luce, has been greatly recommended by some

who have had an opportunity of seeing cases of bites from the serpents of the tropics; how far it really is superior to the common carbonate or compound spirit of ammonia, and on what this superiority depends, I must leave for those who have watched its action and effects to determine.

REPORT OF CASES.

By H. M. HUGHES, M.D.

Physician to the Surrey Dispensary.

Fever.

THE district to which the charity of the Surrey Dispensary is extended, or rather within which patients may be visited at their own residences, embraces the whole of the space bounded on the North by the Thames, within the line passing from the Vauxhall to the Kennington, Walworth, and Green Man Turnpike Gates, along the Blue Anchor Road to the Mill-pond Bridge. This is divided nearly equally, as to extent, into an eastern and western district, by the road leading from the Walworth Gate to the London Bridge. It is with the western district alone that, during the past year, I have been connected; and it is to that, therefore, alone, that the following observations strictly apply, though I believe that they would be for the most part applicable to the eastern district also. The patients visited by me have, however, in the great majority of instances, resided within the triangular space, bounded by the roads passing from the London and Westminster Bridges to the Elephant and Castle. Their places of abode have usually been in confined courts, alleys, or back streets, in which ventilation is imperfect, cleanliness is generally little regarded, and the *res augustæ domi* is often painfully evident both without and within.

In this institution, as generally in others of a similar kind, those patients alone who are too ill, too weak, or are otherwise unable to attend personally at the Dispensary, are visited by the medical and surgical officers at their own homes. A very large majority, therefore, come to the Dispensary. Among those visited at their own residences by myself during the year, between March 16th, 1839, and 1840, I have longer or shorter notes of 223 cases.

These cases I have arranged in a

tabular form, and propose, after making a few general observations upon the diseases mentioned in the table, as presented to my own notice, briefly to relate any particular case which may appear to me to possess any especial interest. Before doing this, however, I may, perhaps, with propriety make a few general remarks upon the diseases occurring under my observation during the past year.

It has, I believe, been commonly noticed by medical practitioners of the metropolis and its vicinity, that the state of the public health has been unusually good during a great portion of that period; and that epidemic and contagious affections have been both few in number and slight in character. My own observation certainly tends to support the correctness of this opinion. Continued fever has not been nearly so common as usual; and typhus, usually so frequent in dispensary practice, has been a comparatively rare disease. In confirmation of this, I may, I believe, with truth assert, that I have not unfrequently had under my care at one time, and in the same charity, more cases of typhus than have occurred to me during the entire year. It is true that previously to the past year I was engaged in the eastern portion of the dispensary district, from which the patients are somewhat more numerous than from the western, and in which typhus may be generally more common than in that with which I am now connected; but neither of these circumstances are sufficient to account for the small proportional number of cases of fever. It has also been, I believe, a common observation at Guy's Hospital, that the wards, for the last twelve months, have been unusually free from fever. For the last thirteen years, during which I have had the advantage of pretty constantly seeing the patients in that institution, I do not recollect so few persons to have been admitted with that complaint in any equal space of time as during the past year. Scarlatina, in the latter part of the summer, and during the autumn months, was very general, at least among the poorer classes; but though I have heard of a few fatal cases on the Surrey side of the Thames, it has usually been of a very mild form; so mild, indeed, that, in many instances, the parents of the children affected have not sought for any medical assistance. Measles and hoop-

ing cough have been less common; and of small-pox I have seen and heard of but very few examples. The complaints most common have been those resulting from the more obvious changes of the atmosphere, as chronic affections of the chest, and rheumatism. In reference to the following table, I may observe that I have introduced in the line "relieved," not only those patients who were dis-

charged relieved, but also all who have gone into hospitals, or to the country, who have left the district, or who, being able, after some amendment, to come to dispensary, have discontinued their attendance, and have omitted to return their letters of recommendation. Several of these I have reason to know were cured; and some, it is probable, have subsequently died.

Fever, intermittent.—Two cases of this form of fever are noted in the table as having been of a character sufficiently severe to require visiting at home. Ague is a disease not usually needing the attendance of the physician at the bedside of persons under its influence. The complaint, in both instances, occurred in the person of one individual at different times, and, as on these occasions, it presented some peculiarities, I shall briefly relate the particulars. A lad, of strong constitution, and good health, aged 17, left his parents to practise his calling (a wire worker and tinker,) in the eastern and midland counties, and returned, after an absence of several months, very ill. When first summoned to attend him, April 30th, 1839, I found him labouring under all the symptoms of common continued fever of a severe kind: his face was flushed, and his conjunctiva injected;

there was great heat and pain of the head, a burning skin, great general vascular excitement, and considerable disturbance of the sensorium; the tongue was white, but moist, and the pulse about 112. This state had been preceded by languor, sickness, general pains, and shivering. Six or eight leeches were applied to the temples; the hair was ordered to be cut, and an evaporating lotion to be applied to the head; a dose of castor oil to be taken directly, and a mixture containing soda three or four times a day. After a quiet night, I found him the next morning nearly well, and I began to suspect that he had formerly laboured under the effects of simple cerebral congestion, or that he offered an example of one of those rare cases in which fever seems to be cut short. On the following day, however, after passing a restless night with considerable wandering delirium,

he was as severely affected with fever as before. This state of febrile excitement was neither preceded by any distinct rigor nor followed by diaphoresis; but as I found that, on alternate days, he was comparatively free from complaint, and entirely free from fever, being only affected with slight languor and debility, after I had acted freely on his bowels, I gave him quinine in doses of three grains every six hours. From this time he speedily recovered, and afterwards had but one paroxysm of a much milder character than before. In a week, being apparently well, he discontinued his medicine without my sanction, and resumed his occupation and his peregrinations. He again came under my care for the same affection, in a much less severe form, June 18th, and was immediately ordered to take quinine. The medicine at once checked the disease; but, on this occasion, he continued it for four or five weeks after the apparent removal of his complaint, and he has from that time remained perfectly well. If this can fairly be considered a case of ague, it certainly presented some peculiarities, as well in the great severity and long duration of the paroxysms, as in their being neither preceded by shivering nor followed by perspiration. On the alternate days, however, he was entirely free from all febrile excitement.

Fever, remittent.—The only four cases of this complaint, requiring visiting at home, occurred in children, and presented nothing remarkable. They, together with almost all the cases of a similar kind, which I have seen, appeared to prove the correctness of the opinion, which places the source of the remittent or irritative fever of children, in disorder of the stomach and bowels, produced by unhealthy secretions or improper food. I have usually found them easily yield to small doses of Hydrarg. c. Creta and Rhubarb at bed time, a little castor oil in the morning, some simple saline medicines during the day, and regulation of the diet.

Fever, continued.—The cases of this form of fever, falling under my care, during the past year, have, as I have already mentioned, been fewer in number than in any equal space of time, since I have been connected with dispensary practice. They have also certainly been less severe in character, than in those seasons in which fever is epi-

demic. This statement may appear inconsistent with the fact of two deaths having occurred in only thirteen cases, of which notice is taken above, as the proportion is certainly larger than under ordinary circumstances. Death, however, in one at least, if not in both, of these cases, appeared to me, and, I think, will probably in the sequel appear to others, to have been connected with other causes than the simple fever.

The respective ages of the parties attacked were 5, 7, 14 (3), 16 (2), 17, 32, 33, 36, 42, and 62. Of these, five belonged to one family, and two to another; the other cases were single and distinct. Of the thirteen, muco-enteritis existed in five; in one of whom it was so severe as to threaten exhaustion and death. In the majority of instances, at some part of the complaint, there was visible on the trunk a measles-like rash, which, as far as I was able to observe, appeared and disappeared at uncertain periods, and presented no regularity in either its extent or its duration. In none of these cases did true petechæ make their appearance on any part of the body; though in one case, that of a lad aged 16, who suffered from a very violent attack of the complaint, there appeared, on the fourth day, some large spots of a damask rose hue, resembling the roseala autumnalis of Willan. They were confined to the upper extremities, disappeared on the sixth day, and were replaced on the eighth by the more common rash of fever, which, though most thick upon the arms, was also visible on the trunk and lower extremities. It has been supposed that this rash is almost exclusively seen in those cases of fever which are accompanied with muco-enteritis, and thereby resemble the disease as it generally appears in Paris. The connection of the two affections does not appear to me to be clearly established, as I have not unfrequently seen the rash, without any important irritation of the stomach or bowels; and have often witnessed well-marked and serious complications of "gastro-enterite" without being able to detect the slightest appearance of the rash.

The treatment I have adopted in all cases of simple fever has been pretty uniformly the same, and has been essentially of the "médecine expectante" kind. My object has been safely to guide the patient through his complaint, by meeting and combatting symptoms as they

arose, rather than by the adoption of strong and active measures, and the employment of heroic remedies, to expose him to a chance of greater danger, with the vain hope of cutting short the complaint. In almost all cases, the hair has been cut short, or the head shaved, and cold evaporating lotion applied to the scalp, according to the amount of heat, pain, or heaviness of the part. The bowels have been opened by castor oil, and an occasional dose of Hydr. c. Creta, and when diarrhœa has existed, it has been checked by chalk mixture. The common medicine prescribed has been 12 or 15 grs. of sesquicarbonate of soda, in mint water, three or four times a day. At a time varying from the seventh to the twelfth day, according to the age and vigour of the patient, support, in the form of beef tea and arrow root, has been prescribed, and stimulants administered. These have been repeated or temporarily withheld, according to their effects. Under this simple plan, the complaint has generally proceeded to a favourable termination. If decided evidence has existed of inflammation of the mucous membrane of the ilium, the application of six or eight leeches over the part affected, with fomentations, and a starch enema, with ʒj. or ʒij. of syrup of poppies, or ℥xv. or xx. of laudanum, repeated once or twice daily, has usually been efficient in removing it.—Whether the soda has really been beneficial, by altering and improving the condition of the blood, as is believed by Dr. Stevens and others, or whether its virtues are simply negative, and its operation purely passive, I have not yet had the opportunity of deciding, but intend to submit to the test of experiment, as far and as fairly as I can conscientiously do so. That patients suffering under the simple continued fever of this country generally progress well under the use of soda, can be attested by cases so numerous as not to admit of doubt; but I am not aware that it has yet been proved that they would not do equally well, if simple medicated water were alone administered; the same precautions being used in both cases, to remove any complication that may arise. The most difficult matter in the treatment of fever has ever appeared to me, to decide upon the proper time for commencing the administration of stimulants. I have not had sufficient opportunities of testing the mode of arriving at a decision upon

this important point, proposed by Dr. Stokes, to be able properly to estimate its advantages; but from the very few cases in which I have applied it, I am led to fear that it will not be found so generally and so practically useful, as that gentleman's personal observation induced him to believe. When doubt has existed, I have hitherto found it desirable to commence with the mildest form of stimulant; and carefully to watch its effect. For this purpose I have sometimes used the tincture of calumba, which I have often seen prescribed, under similar circumstances, by that excellent practical physician, the late Dr. Cholmeley: and on other occasions have ordered the simple infusion of serpentry. If these have been borne without injury, or with advantage, the quantity has been increased, or ammonia and wine have been cautiously added with good effect.

The following case is perhaps worth recording, in consequence of the painful affection which succeeded the fever:—

Theodosia Forster, aged 14, a thin, delicate girl, was first seen by me August 6th, 1839; and was then in the fourth or fifth day of fever, for which she had been attended by a practitioner in the neighbourhood. Her complaint was accompanied with vomiting and diarrhœa, red tongue, tenderness at the scrobic. cordis, and in the right iliac fossa; and other symptoms of inflammation of the mucous membrane of the stomach and bowels. Leeches were ordered to be applied over the cœcum, and a large thin linseed poultice over the abdomen; gr. iiss. of Dover's powder were given at bed-time, and chalk mixture and arrow-root during the day. The next morning, the tenderness was much less; but the diarrhœa continued. She was already much exhausted, and I feared that she would not have sufficient power to support the continued drain to which she was subjected. She was ordered

Syr. Papaver. ʒj. Decoct. Amyli ʒij. M. ft. Enem. statim injiciend. et repetend. vespere si opus fuerit. Inf. Serpentar. ʒiiss. Syr. Papaver. ℥xx. Conf. Arom. gr. xv. 6tis. horis sumend.
Mist. Cret. ʒiiss. Vin. opii. M. iij. Conf. Aromat. gr. x. pro re nata urgente diarrhœa. Contr. Catapl.

On the 8th, the diarrhœa had in a great degree ceased, but she was troubled with frequent vomiting, on account of which, acid. hydrocyan. dilut. ℥ij.

were added to her tonic mixture. Under the use of this medicine, together with from three to five grs. of Dover's powder at bed-time, she continued to improve till the 13th, when she complained of a suddenly supervening and very acute pain, in the middle of the inner side of the right thigh. There existed not the slightest tension or redness, though the exquisite tenderness rendered it impossible to examine it minutely. She was perfectly incapacitated from raising or otherwise moving the thigh; but did not suffer from passive motion, if the part affected was not touched. She had no pain on rotating the thigh outwards, or on firm pressure being made upon the trochanter major; nor any inconvenience from examination of the knee, the hip-joint, or the groin. The pain was supposed to be neuralgic, and she was ordered to continue her medicine, and use an opiate liniment. On the 15th, the pain was even more acute; and now affected the knee as well as the thigh. Still no tenderness could be discovered about the hip joint, and there was not the slightest febrile excitement; but as some tenderness was felt on pressure being made over the sacrum, a blister was applied to this part, and a belladonna liniment ordered for the thigh and knee. A little temporary relief was afforded by the blister; but no permanent benefit resulted. Vapour baths were afterwards used with much benefit; but their good effects were of short duration. On the 29th, the pain was equally severe, and the inability to use the limb as perfect as before. She had no quiet rest, and her sleep was almost entirely prevented. Forcible rotation outwards, and firm pressure on the trochanter, still caused no inconvenience; but I now discovered that there existed some tenderness on pressure over the hip-joint, in the groin. Leeches and fomentations were therefore applied to this part, and a blister behind the trochanter. Relief decided but only temporary was obtained. Her general health being now good, with the exception of the debility kept up by the continued pain of the thigh, of which she alone complained, she was transferred to the care of the surgeon. This gentleman ordered a repetition of the leeches, and subsequently applied strengthening plasters, spread upon thick leather. After three months she was sent into the country, and now feels no incon-

venience from her former local affection, excepting a little stiffness in the hip in cold weather, and after more exertion than usual.

The two fatal cases were the following:—

M. A. Johnson, aged 42, a short, rather stout woman, of healthy appearance, after nursing her daughter in a severe attack of continued fever, became herself the subject of that disease, July 2nd, 1839. Under the ordinary treatment, mentioned above, she went on exceedingly favourably till the seventh or eighth day of her complaint. Her tongue was indeed dry and black; but her pulse was by no means very feeble. She was not troubled with cough, had no diarrhoea; neither did she labour under any important head affection, being subjected only to slight delirium at night. She was taking serpentary and ammonia with apparent benefit; in fact she had not a single bad symptom, excepting a settled and expressed conviction that she should die. It has been quaintly observed, "that patients who are determined to die, are rarely disappointed," and however it may be explained, the fact is certain, that persons upon whom this settled conviction rests, in acute diseases at least, very rarely recover. This patient was not an exception to the general rule, as upon calling on the eighth or ninth morning I was informed that she had been seized with a fit during the previous night, and had suddenly expired. No examination was permitted.

John White, aged 33, a large powerful man, came under my care March 5th, 1840. He was by occupation a coal-heaver, and of very intemperate habits. A week before I saw him, he was prevented going to his work by shivering head-ache, and pains of the bones. Two days after, his head became more severely affected, and the following day he was seen by a practitioner, who believing, from the symptoms, that he laboured under cerebral congestion, bled him to xxx and administered an active purge. The next day he was much relieved, and was not again seen by any medical man, till the eighth day of his complaint, by myself; when he was lying on his back, with a flushed and purple face, and dilated and sluggish pupils; his senses were obtuse, but he answered intelligibly to questions proposed, and complained of head-ache,

sore throat, and tightness of the chest, which was quite resonant on percussion, but over the whole of which a large mucous rattle was distinctly audible. The skin was hot and dry, and on the chest and abdomen were sprinkled a few pink and measles-like spots; the tongue was coated and moist, not red at tip or edges; pulse 112, full, but feeble.

Appl. Empl. Cantharid. sterno. Lotio Evaporans fronti et Capt. Antim. Potassio Tart. gr. $\frac{1}{2}$ Sodæ Sesquic. gr. xij. Julep Ment. ζ iss ter die.

7th.—Little alteration—bowels relaxed—cough troublesome.

Ext. Conii gr. iij. Pil Hydrarg. gr. j. Pulv. Ipecac. gr. j. M. ft. Pil. 6tis. horis sumend. Mist. Cretæ, pro re nata. Arrow Root.

8th.—Bowels less relaxed—pulse more feeble—pupils dilated—some delirium at night—lips dry, and sordes about the teeth—lay in a lethargic state, but could be roused.

Empl. Lytiæ nuchæ applicand. R. Inf. Serpentariæ ζ iss. Ammon. Sesquicarb. gr. iij. Conf. Aromat. gr. x. 6tis. hor. Beef tea and arrow root.

9th.—Much the same. He suddenly and unexpectedly expired in the evening. After taking some beef tea, with some relish, and apparent benefit, he was left for a few minutes, and upon the return of the attendant was dying. No examination was permitted.

ON THE PREPARATION OF EXTRACT OF CONIUM.

To the Editor of the Medical Gazette.

SIR,

Some few years ago I was particularly struck with a paper which appeared in your pages, from the pen of Mr. Richard Battley, containing an account of some experiments on conium, and its preparations.

The views he took seemed to me so new, and the reasoning he adopted so feasible, that I have been induced to investigate the subject.

Upon referring again lately to the paper, I find Mr. Battley is of opinion, that the action of conium is dependent upon the green resinous matter which it contains, as the following extract will shew:—

“The medicinal properties being thus evidently contained in the green resinous matter, the question arises, in what form it can be most beneficially administered? The present mode of preparing the extract, by evaporating the expressed juice till it acquires a proper consistence, is obviously defective.”

That the ordinary method of preparing the extractum conii is objectionable and greatly defective there is no doubt; but to suppose that the action of the extractum conii is dependent upon the green resinous matter, is an assertion, I think, not borne out by experience.

I have paid some attention to the preparation of this extract, because its value is, I consider, not duly appreciated by medical practitioners, probably from the careless and defective manner of manipulating. From personal observation I am inclined to believe, that the action of conium depends upon the quantity of conine which it contains; and, if such be the case, that preparation will be the most certain and efficacious which contains the largest quantity of this active principle. I am well aware that most pharmacists entertain the same idea that Mr. Battley does, and imagine, that extract of conium, to be good, should possess a beautiful green colour.

This is not at all essential to the activity of the preparation; for, upon examining the extract procured from various sources, those which assumed the worst appearance to the eye, have been found to contain the largest quantity of conine.

In the same volume of your journal will be found a paper, read by Mr. Judd to the Medico-Botanical Society of London, on the strength of various vegetable preparations; and amongst them the extractum conii is mentioned: compared to that procured from Mr. Squire, Mr. Battley's was found to be minus in activity, although possessing a beautiful green colour.

The best and most effectual mode of administering conium is, I conceive, by expressing the juice, and preserving it with alcohol; some of which I have had the honour of submitting to the best authorities on the subject: which, although resembling in colour the tinct. zingiberis of the London Pharmacopœia, contains a very large quantity of conine, and is a very energetic and certain preparation. To ascertain whether conine be present in the extract, it is only necessary to rub a small quantity in a glass

mortar with liquor potassæ, when a peculiar odour, somewhat resembling animal oil, will be given off; by bringing the vapour of hydrochloric acid in contact with which, dense white fumes will be given off, clearly demonstrating the presence of conine. The evaporation of this juice under the exhausted receiver of an air-pump, produces an extract of a dullish brown colour, but possessing great power, which can only be referred to the conine which it contains, and which may be readily recognised by the above admirable test, first proposed by Dr. Osborne.—I am, sir,

Your obedient servant,

EDWARD BENTLEY,
Oper. Chemist to H.R.H. the
Duke of Cambridge.

Laboratory,
41, Moorgate-street,
May 4, 1840.

RUPTURE OF THE UTERUS.

To the Editor of the Medical Gazette.

SIR,

The following case may be interesting to some of your readers. Your inserting it in your journal will oblige

Your most obedient servant,

JOHN JACKSON, M.D.
Lecturer on Forensic Medicine.

Glasgow, 21, Maxwell-Street,
April 27, 1840.

On the afternoon of 6th April, 1840, I was sent for to attend Mrs. C—— during her confinement. She was a stout healthy woman, 32 years of age, and had borne five children. Her recovery from her last labour had been protracted, which she ascribed to violence used by the midwife when extracting the placenta. On my arrival, I learned that she had experienced regular pains since ten o'clock, morning. By examination, I found the os uteri dilated to the diameter of a shilling, and the presentation to be natural. The pains were neither frequent nor severe. Seeing no need of my constant attendance, I left her, promising to return at ten o'clock in the evening. On my return, I was told that the labour, during my absence, had been progressing, and that the pains were getting somewhat severe and bearing down. The os uteri was felt to be well dilated, the head entering the pelvis. The labour continued to go on favourably. The pains were regular, and effective in advancing the head, but

in no way unusual. By two o'clock next morning, "the bag of waters" was protruding from the vagina, the head was nearly on the perineum, and every thing prognosticated a safe and immediate delivery. Soon after, the membranes burst, and a quantity of water was discharged. The pains now ceased; she got anxious and impatient, complained of cramp in the left leg, and desired to be instrumentally delivered. The pulse was weak; the skin cold and clammy; the countenance pale and death-like; the breathing embarrassed, and accompanied with a mucous rûle. The abdomen was somewhat prominent and irregular, not painful on pressure. No part of the fœtus could be felt immediately under the abdominal parietes. The head had not receded. A small quantity of blood had, for the first time, escaped from the vagina. Not being able to account for these symptoms, except on the supposition that the uterus had been ruptured, I thought it proper to attempt to save her life by immediate delivery. I called in the assistance of my friend, Mr. Boag. With his sanction, and the consent of the husband and patient, I proceeded to deliver. I applied the forceps, but they slipped. I then opened the head, and delivered with the crotchet in a few minutes. The child was of the full size, and of the male sex. The cord was round the neck. The placenta shortly after came away, with a little traction. She died at half-past five.

Thirty-two hours after death, I inspected the body, in the presence of Messrs. Boag, Douglas, and Jackson. The abdomen contained about 2 lbs. of dark coagulated blood. On raising up the uterus, a longitudinal rent was seen in its posterior inferior part, passing through the centre of its cervix. Four fingers could be easily passed through the rent into the cavity of the uterus. On measurement, it was found to be four inches in length. The coats of the uterus were healthy, but quite destitute of blood. The viscera of the abdomen were normal.

This melancholy case tends to shew that rupture of the uterus may take place without any symptom leading us either to fear the approach of such a terrible accident, or to become immediately sensible of its occurrence. The case was apparently a very favourable one: the presentation was natural; the pains

were regular and effective, but not unusually powerful; the os uteri was fully dilated; the waters were formed, and the head was well advanced. She did not complain of pain fixed in any one particular part, neither was she restless nor crying out "that she is ready to burst if something be not done for her." When the uterus was ruptured there was no particular symptom, and I, after a little time, was convinced of its occurrence as much by negative as positive symptoms. She did not feel any thing giving way within her; the head did not recede, and no part of the fœtus could be felt immediately under the abdominal walls. From this case, then, I am inclined to think that rupture of the uterus occurs much more frequently than is suspected; most medical practitioners having been led to expect that it is marked by some decided symptoms. I am corroborated in this opinion by a very able accoucheur of this city, who lately mentioned to me, that he has been called in consultation in nine cases of ruptured uterus, and in no one case was its true nature known before he saw the patient, notwithstanding two, and sometimes three, surgeons had been in attendance.

TALIACOTIAN OPERATION.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following successful case of Taliacotian operation, sufficiently interesting for a place in your valuable journal, will you oblige me by its insertion.—I remain, sir,

Your obedient servant,

W. H. SLAGGETT,
Dresser.

London Hospital, May 11th.

Henry Osborn, æt. 7, was admitted into the London Hospital on February 25th, under the care of Mr. Scott.

On the 23d inst, he fell with a jug in his hand, the fragments of which, in his fall, excised the whole of the cartilaginous part of the nose, at its junction with the nasal bone, at the same time cutting out a triangular piece of the upper lip. He was not brought into the Hospital until the 25th inst., at which time the wounds were all healing. Ordered warm water dressing.

April 3d.—The wounds being healed,

and the child's health good, at 2 P.M. Mr. Scott performed the Taliacotian operation in the following manner.

The proper size of the flap was first marked in ink on the forehead, and formed a triangle, extending over the centre of the forehead, the apex being situated over the nasal process of the frontal bone. An incision was first made through the integuments and muscular fibre, to the periosteum, from which latter it was reflected, remaining attached to the forehead by a neck of skin. The flap was turned down, so that the skin was placed externally, and united to the already pared edges by fine ligatures. A septum was then formed by a longitudinal piece being cut out of the upper lip, and turned up to meet the flap, with which it was united by a pin and ligature. The divided edges of the lip were brought together by hare-lip pins, and a plug introduced on each side of the septum, so as to keep the opening of the nares patent. The whole was then lightly covered with Emp. Plumbi, and lint, wetted with warm water, ordered to be kept constantly applied.

6, P.M.—The child being very restless, Tr. opii. grtt. v. were given.

6th.—The dressings were removed this morning; the new nose is completely united to the original structure; the septum is also united. The wound on the forehead is granulating. The pins and ligatures are all removed, and the wounds dressed with Emp. Plumbi, warm water being kept applied to the nose and forehead. The plugs are re-introduced.

April 21st.—The neck of integuments, communicating with the forehead, was divided this morning: the child's health is good.

May 6th.—The nose has entirely healed, having been dressed daily, and the plugs kept constantly in the nostrils.

OVARIAN DROPSY.

PARACENTESIS PER VAGINAM.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case worthy of a place in your valuable journal, it is much at your service.

I am, sir,

Your obedient servant,
JAMES OGDEN, Surgeon.

Rochdale, April 28, 1840.

Mrs. Jackson, æt. thirty-two, the subject of the present case, had been generally healthy until the birth of her last child, about five months previous to the date of her present illness, when the catamenia ceased. On the first intimation of her illness she felt sickness of the stomach, was averse from exercise, and had urgent thirst, with scanty urine. About two months previous to these symptoms, she had a sense of considerable fulness and swelling, which, from her description, seemed to arise out of the pelvis, extending at length from the left side of the pelvis to the umbilicus: on examining the abdomen, no pain was elicited by pressure. She was induced to believe that she was pregnant, and consulted me particularly on that subject, as well as on account of much difficulty which she experienced in passing her urine; and this, together with other symptoms, she ascribed to a nephritic origin. The difficulty in relieving the bladder increased to such a degree as to require the use of the catheter, and on making the attempt I found it utterly impossible to pass it, on account of the tortuous state of the meatus urinarius. On examination per vaginam, I discovered a tumor occupying the hollow of the sacrum, and allowing little more than a finger to pass between it and the pelvis. A segment of the os uteri could with difficulty be felt above the pubes, which led me to suppose, on the first impression, that there was retroversion of the uterus. On the left side of the vagina I found an elastic tumor, which I at first took to be the fundus of the bladder. No urine had been passed for more than twenty-four hours, and as the patient was now suffering extreme pain in consequence, I was somewhat alarmed for the safety of the bladder, and called to my assistance Mr. Beeckley, surgeon, of this town, who, as well as myself, made several fruitless attempts to pass the catheter. In this dilemma, I punctured the bladder above the pubes, and abstracted two pints of high-coloured urine. In six hours after, as no water had been evacuated per vias naturales, I again attempted to pass the catheter, and was again foiled. On a second consultation we determined to puncture the tumor in the vagina, being now convinced that we had an ovarian disease to contend with, and as a speedy removal of pressure was necessary, we agreed to pass a trochar into the tumor in the vagina, and

drew off four quarts of a semi-transparent fluid, which gave the patient great relief and restored the action of the bladder, she being able to void her urine in an hour after the operation: the discharge from the ovarian sac continued for several days, and a permanent cure followed. She has never menstruated since the catamenial suppression, which occurred five months before the operation was performed, notwithstanding which she has, with the aid of occasional bleeding, enjoyed good health up to a late period. The fact of paracentesis per vaginam having proved a permanent cure for this disease is however rare; and although we cannot possibly expect the like to be the case, where there are many cysts in a state of progressive enlargement, where the accumulated fluid is of a morbid character, or where there is any other diseased organization of the ovary, still the rationale of the cure in the present case becomes an object worthy of inquiry, and the multiplication of facts tends to facilitate the desired explanation.

RUPTURE OF THE INTESTINUM ILEUM.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case of rupture of the intestinum ileum, from the kick of a horse, sufficiently interesting for a place in your journal, you will oblige me by its insertion.

I am, sir,

Your most obedient servant,

THOMAS WILLIAMSON, M.D.

One of the Physicians to the Leith Dispensary,
and Edinburgh and Leith Humane Society, &c.

Leith, May 7th, 1840.

John Slater, æt. 19 years, a stout healthy young man, by occupation a carter, was reported to have received a kick on the abdomen from his horse, on the evening of Friday, the 1st May, about 9 o'clock, whilst taking him into his stable for the night. Immediately upon the receipt of the injury, he complained of severe abdominal pain, and walked with little assistance to a friend's house (a distance of about one hundred yards), where he passed the night in great anguish, owing to the abdominal pain, with excessive and continued

vomiting, the latter symptom having made its appearance about two hours after the accident. About 7 A.M. on the morning of Saturday the 2nd, he left the house where he had passed the night, and walked, with the help of his sister, to his own house, a distance of about three hundred yards more: immediately upon his arrival, I was requested to visit him, which I did without delay, and found him still complaining of the abdominal pain, the principal seat of which he referred to the umbilical region; this pain was greatly increased by the slightest pressure of the hand, and also during the efforts made to vomit. The fluid vomited was of a yellowish colour, and in great abundance, owing to the large quantity of liquids which he drank, in order to satiate an intolerable thirst; pulse full, 120 beats in the minute; tongue natural; countenance expressive of great suffering and anxiety; no external mark on the abdomen to be perceived. As all the symptoms indicated acute peritonitis, and considering the state of the pulse, it was deemed advisable to abstract blood from the arm; accordingly a vein was opened, but ere three ounces had flowed, the impression made upon the pulse was so powerful, as to render it necessary to abstain from abstracting more; for now it was almost imperceptible, and about 80 beats in the minute: notwithstanding, as the pulse in some degree rallied, and as the pain was nothing abated, leeches and a large blister were applied to the abdomen, and a laxative enema ordered to be given. About 1 P.M. of the same day, all the symptoms were aggravated, and the pulse scarcely countable; no abdominal tumor, or tympanitic distension, could be detected; the enema had been retained without effecting any good; urine passed freely. Mustard sinapisms were now applied to the inner surface of the thighs, with other remedies, but all to no purpose, as he continued sinking till 6 P.M., when he expired, twenty-one hours after he had received the accident, retaining all his intellectual faculties unimpaired to the end.

Dissection, 25 hours after death.—The abdomen, which was now greatly distended, being laid open, a large quantity of air made its escape: upon reflecting the abdominal parietes, no extravasated blood was observed under-

neath the peritoneum (as is sometimes seen in similar cases); the peritoneal cavity contained about two pints of a brownish coloured serum, with large masses of soft, and recently formed coagulable lymph floating in it; the peritoneal covering, throughout its entire extent, was the seat of very active inflammation, and covered here and there with lymph: none of the fecal contents of the intestine were visible in the abdominal cavity. Upon tracing the bowels from the duodenum downwards, we arrived at the ileum, which was found collapsed; and here, at its inferior third, we detected the seat of all the mischief, for it was now evident that this bowel had been completely torn across, so low down as its mesenteric attachment: the edges of the laceration were dark-coloured, and irregular, and altogether free of lymph deposit; no appreciable quantity of blood had followed this laceration: all the other abdominal organs were healthy.

REMARKS.—The case now described is one of considerable interest, as well from its rarity, as other circumstances connected with it. Without entering at all into any lengthened remarks, those who have perused the history of the case, as well as the appearances observed at the subsequent post-mortem examination, cannot fail to observe the total want of connexion between the severe internal lesion of the bowel, and the appearance of the external abdomen; for, as we have previously observed, not the slightest evidence existed externally, by which we could have at all hazarded the opinion that the abdomen had sustained so severe a blow as to produce the rupture of the bowel internally. It is well known that the liver and spleen may be ruptured by means of external mechanical violence from a blunt instrument, without the development of ecchymosis, or extravasation of blood into the tissue of the parietes of the abdomen: this important medico-legal fact can comparatively be easily understood and explained, when we consider the solid nature of the texture of these organs, as well as their relative position to the external part, which may have been the direct recipient of the blow; but, in the case before us, we have, in the first place, an object not of a very blunt nature, or rounded form, as the instrument by means of which the blow was inflicted, but on the contrary, in some places, angular and

pointed; yet, notwithstanding the internal mischief produced, we had not the slightest trace or evidence of external ecchymosis or extravasation; and in the second place, instead of having a comparatively solid texture, as the liver or spleen, we have the intestine (especially if moderately distended with air), presenting all that in our opinion *à priori* would lead us to infer it as being less likely of rupture from external violence; for, just in proportion as the quantity of air becomes diminished in the lung during pneumonia, and its place supplied with blood, does its friability of texture, and resemblance to the liver, increase: so that one would naturally infer, that the intestine was most dissimilar to the liver in this respect, in so far as, containing air, it would the more readily yield to the external blow received; it is, however, always more easy offering hypotheses or theories, than advancing satisfactory and reasonable explanations of phenomena sometimes observed. What can account, then, for the extensive rupture of which the ileum in this case was the seat? Are we justified in referring it to an *inordinate* distension of the intestine by air, at the time of the receipt of the injury? or, can we in any way ascribe it to the fact of the bowel at the time containing a larger quantity of *chyme* than usual, and thus diminishing the amount of its aerial contents? Whatever the true solution of the question may be, it is somewhat singular, that the ileum should oftenest prove the intestine most prone to rupture from external violence or blows. As death usually takes place very rapidly, in cases of perforation or rupture of the intestine, not so much directly from hæmorrhage or extravasation of the intestinal contents into the peritoneal sac, as from failure of the heart's action owing to the extreme depression of the nervous system, it may not perhaps be out of place to remark, in illustration of this, the very rapid and signal impression made upon the pulse, by the abstraction of only two or three ounces of blood, for, it will be recollected, that the pulse, previous to the vein being opened, was full (though not bounding), and that after the patient had lost the above quantity, it became feeble and thready.

PHYSIOLOGY OF THE IRIS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case and observations appear to you deserving of a place in your valuable periodical, I shall be obliged by your inserting them.

I am, sir,

Your obedient servant,

W. P. BRODRIBB, M.R.C.S.

12, Bloomsbury Square,
May 9, 1840.

Whilst the phenomena of disease throw light on physiology, often confirming us in our opinions, and enabling us to regard many points as established truths, they not unfrequently shew us the imperfection of our present knowledge, and prove that much still remains to be investigated. This is the case with the functions of the iris of the eye. The generally received opinion respecting the physiology of this membrane, is, that by enlarging or contracting its pupillary opening, it can regulate the quantity of light admitted into the eye, according to the sensibility of the retina. That it performs this office is sufficiently obvious; yet disease presents circumstances which must be considered exceptions to this notion, and not to be explained by it. I have at the present time under my care a patient whose irides are in opposite conditions, and each iris the very reverse of what might be expected. The right eye is completely amaurotic, so as not to be able to distinguish light from darkness; yet the pupil is but slightly dilated, and the motions of the iris not much impaired. On the other hand, vision in the left eye is uninjured; but the pupil is very widely dilated, and the iris perfectly immoveable. When light is admitted into this eye, its iris remaining fixed, the pupil of the amaurotic one is seen to contract. The case is one of disease of the brain, and the circumstances are as follow:—In February last I first saw the patient, a young man, 30 years of age, of shattered constitution, from the combined effects of syphilis and the long continued use of mercury.

For some weeks he had suffered severe pain in the head, principally in front, though not confined to that part. To this succeeded erysipelas of the head and face, attended with fever, delirium,

&c. which left him in about ten days, when he first discovered that the sight of the right eye was gone. It was at this period that I first saw him, but whether the loss of sight was occasioned by the late more violent attack, or by the previous disease, I could not ascertain. No treatment controlled the disease, and in about five weeks more a drooping of the upper eyelid of the left eye was observed, which gradually increased until complete ptosis was formed, succeeded by paralysis of all the parts supplied by the third pair of nerves. The levator palpebræ lost all power to elevate the upper lid, and (with the exception of being able to turn it outwardly), from paralysis of three of the recti muscles and one of the oblique, the ball of the eye became fixed, so as to render it necessary to turn the whole head towards any object to be looked at. The ciliary nerves being supplied by the third pair, the motions of the iris were destroyed, and the pupil largely expanded. Such opposite conditions of the two eyes, each presenting circumstances at variance with the generally received physiology of the iris, render the case striking. There is nothing extraordinary in a contracted state of the pupil in amaurosis, as it sometimes occurs, yet such cases are exceptions to the general rule. Moreover, certain diseased conditions of the brain, in which there is no sensibility of the retina, furnish other instances of the pupils being similarly contracted. Dr. Baillie has recorded cases of apoplexy in which they were reduced to mere pin-hole apertures, and I have seen one instance of the kind myself; and generally, I believe, such a symptom is regarded as peculiarly fatal. In profound coma, produced by drinking a large quantity of ardent spirits, the pupils are sometimes much contracted, although more commonly dilated and insensible. Also in poisoning by opium, where complete coma exists, the same contracted state is generally observed. Such cases constitute a large number when assembled together, and although they may be considered as exceptions to a general rule, yet they must take place in obedience to some law at present unknown to us. Physiology and pathology reflect light on each other; and whilst there can be no sound pathology that is not based on the former science, the phenomena of disease furnish us with many proofs of

the deficiency of our physiological knowledge, and at the same time may guide us into right paths for its further improvement.

APPEARANCE

OF HOOPING-COUGH MORE THAN ONCE, IN THE SAME INDIVIDUAL.

To the Editor of the Medical Gazette.

SIR,

As medical knowledge should be beyond all other accumulative, I forward you the following facts:—Master —, aged almost five years, is now affected with hooping-cough, well marked by the characteristic hoop. When an infant of nine months he suffered from laryngeal irritation during dentition; and during his convalescence, hooping-cough, which was affecting three other children in the same family, attacked him. What is not a little remarkable, shewing the constitutional peculiarities in families, I understand, from the evidence of the medical attendant upon the family of this young gentleman's mother, that this lady has a brother and sister, both living, who have had hooping-cough more than once. They both had the disease for the first time when infants but a few months old: in the latter the recurrence took place at the age of seven; and the former caught the disease from children, his nieces, when he was five-and-forty years of age.

I am led to trouble you with the above particulars, from noticing the discrepancy of opinion among some standard authors on the subject. Dr. Copland, in his very valuable Dictionary, defines hooping-cough "as appearing but once during life;" Dr. Underwood says, it "never appears a second time;" Dr. Mannsell observes, in a qualified way, "the affection being one of those which *regularly* occur but once in the same individual;" and Dr. Guersent infers, from his immense experience at the Hôpital des Enfants Malades, that "il est rare qu'on l'ait plusieurs fois dans sa vie; cependant, j'en connais plusieurs exemples." (Dict. de Med. art. Coqueluche).—I am, sir,

Your obedient servant,

WM. ENGLAND, M.D.

Wisbech, May 6, 1840.

ON THE
PHYSIOLOGY OF DRINKS,

AND THEIR INFLUENCE ON THE BODY IN
HEALTH AND DISEASE.

BY MELBOURNE B. GALLWEY,
Assist.-Surgeon Royal Artillery.

WHILST the "master builders" of the profession are steadily advancing the science of medicine, and whilst contributions of some sort or other are daily coming in from the general republic, more particularly at a moment when the study of physiology is claiming especial attention, and exercising a practical influence on the treatment of disease, it is not uninteresting to witness the neglect with which subjects, apparently simple, are treated; but on which, in reality, we possess no substantial or positive knowledge. Yet, before we engage ourselves in questions of ultra perplexity, whilst we are busied in our inquiries into the "reflex function of the nerves," into the sources and origin of "animal heat," or in discovering the primary cause of the "respiratory movements," it would be well that we studied to make ourselves familiar with the operations of nature, as they influence the phenomena of hourly observation, and of matters which have relation directly and constantly to our physical interests and necessities, for

"To know
That which before us lies, in daily life,
Is the prime wisdom."—MILTON.

One of the subjects of this latter description, to which the attention of the profession has scarcely, if at all, been directed, is the physiology of drinks or of fluids. Who in the present day halts by the road-side of graver matters, to inquire into the fate of the ample potations we daily consume, to learn how they influence our system in health and in disease? Where shall we look for a writer on the subject? At least, for my own part, I know not where to find one. Physiologists have treated the matter with a levity which is singularly characteristic of their ignorance of the same, or if they have delivered themselves at any length on the subject, no practical, no useful deductions have ensued on their inquiries.

"It is singular," says Magendie, "that physiologists, who have been so much engaged with the digestion of solid food, and who have erected so many systems

to explain it, and made so many experiments to throw light on its nature, have never paid any particular attention to that of drinks; this study, however, presented fewer apparent difficulties than the former." "Fluids," says the same authority, "in respect to the alterations that they prove in the stomach, may be divided into two classes—the one sort do not form any chyme, the other are chymified wholly or in part." That is to say, there are nutritive properties contained within many of the liquids we employ, which render them as suitable for the formation of the chyle as more solid aliment; whilst others again are destitute altogether of such a quality, and in no wise contribute towards alimentation or nutrition. Milk, for example, is absorbed by the lacteals; it is a fluid eminently nutritious, and one which perhaps is converted entirely into chyle. Soups again are an illustration of the latter class of liquids. It is said, and I think there can be no doubt of the fact, that, in the stomach, a separation takes place betwixt the water of which these are composed, and the several ultimate ingredients which endow them with their nutritive qualities. It would seem that the lacteals are reluctant to meddle with liquids, which are not converted more or less into solids in the stomach; and this transmutation of form we observe to be the case with nutritive fluids in general. Thus milk is converted in the stomach into a solid or semi-solid substance by a process of coagulation denominated curdling, and soups having suffered a division in the stomach, viz. into the water and solid materials of which they are made up, the gelatine, osmazome, albumen, &c., (or the nutritive portion of such preparations) are chymified, and subsequently turned into chyle, preparatory to their absorption by the lacteal system of vessels; whilst the water which had entered into the decoction submits to the fate which belongs to that particular fluid, and of which I propose especially now to treat.

That water is absorbed, and ultimately carried into the circulation, must at once be admitted; but in what particular site of the alimentary tract it is so absorbed, is still a sub-judice question; whilst experiment has failed hitherto in determining by what particular system of vessels it is conveyed into the blood. "Water," says Magendie, "mixes whilst in the stomach with the mucus,

the gastric juice, and the saliva, which are found in it. It becomes muddy, and afterwards disappears slowly, without suffering any other transformation; the one part passes into the small intestine, the other appears to be directly absorbed."

Dr. Beaumont, in his remarkable work on Digestion, (a work which must ever claim our respect and attention, from the rare opportunity enjoyed by its author of ocularly witnessing the phenomena which he speaks of and explains,) informs us that he has found water, by experiment, "to disappear totally in less than ten minutes after being swallowed; but whether by absorption or through the pylorus, he was unable to determine." Wilson Philip, in his treatise on Indigestion, appears to maintain that a rapid absorption of water occasionally takes place in the stomach; and Magcagni, somewhere, I think, expresses a similar opinion.

But what are we to understand by the term absorption, as applied to the *disappearance of water* from the alimentary tract? Are we to rest under the assumption that it is taken up by the lymphatics of the stomach, and by the lacteals, in its transit through the intestines, in common with the chyle? This is not an uncommon opinion indeed; it is a view which many of our own countrymen adopt, more perhaps out of deference to Hunter, who inclined to this hypothesis, than that they are in any way able to prove it. Whilst there are others who contend that the absorbents have no power of influencing matters upon which the peculiar operation of the gastric juice has not been exerted; and it does not appear that a liquid, which holds neither animal nor vegetable substance in solution, is affected by that agent; for I may repeat, that the experiments of Beaumont establish the fact, that liquids which are suited to contribute towards alimentation, are converted into a state of solidity or coagulation antecedent to their passage through the pylorus; for example, milk, and the albumen of eggs.

Whether, indeed, the influence of the lacteals and lymphatics extends to such fluids as hold nothing nutritive in solution, is a question which will probably not be decided in our day, if indeed it be capable of solution at all. For experiments wanting apparently nothing in nicety of adaptation, and nothing in delicacy, have extensively been instituted, and that, too, with unwearied industry,

by the opposite factions which have mooted it; and few questions in physiology have been contested and defended by men of more brilliant capacities than has this celebrated one. I say, it will, probably, never be decided, although physiologists are not wanting at the present day, who assert that the question has long been set at rest. Magendie, the father and great agitator of the position, that the lymphatics do not absorb, or are not the only instruments of absorption, imagines he has substantiated it, by the following experiments, and others of a nature not differing materially from it. "Make a dog swallow a quantity of alcohol mixed with water, whilst he is taking his food. If half an hour afterwards its chyle is extracted, we shall see that this liquid contains no alcohol, whilst the blood exhales a strong odour of it, and alcohol may be reproduced from the blood by distillation." Again, "a dog swallowed 4 oz. of a decoction of rhubarb; half an hour afterwards the lymph was extracted from the thoracic duct. This fluid presented no traces of rhubarb; the half of the liquid had, nevertheless, disappeared from the intestinal canal, and there was rhubarb perceptible in the urine." Similar results ensued on making the experiments with a solution of camphor, and other odoriferous bodies. But the experiment, which to myself seems more decisively still to disprove the absorbing power of the lymphatics, as exerted on matters which contain nothing nutritive within them, is that which consisted in insulating a portion of intestine from all connection with the rest of the canal, except through the veins of the part, (taking especial care that no vestige of an absorbent lurked behind,) and filling it then with a solution of nux vomica, when within six minutes afterwards the usual effects of the poison appeared. These experiments would seem, in good truth, to leave little further to be wished for, and little more to be done; and associating them with the collateral facts, which give them additional support, I confess that they are conclusive, in my own mind, as to the correctness of the position taken up by Magendie. There seems to be this imperfection, however, about the experiment first alluded to, viz. that our inability to recognise the alcohol in the chyle is in reality no proof that it has not been amalgamated with it. We can as easily understand how the chyle may refuse to betray its constituent ingredients when

examined, as that analysis would be unable to discover the elementary parts of the food, after they have been finally vitalized into blood.

That liquids possessing no nutritive qualities are unabsorbed by the lacteals, is further borne out by another of Magendie's experiments, which consisted in tying the thoracic duct of a dog, and making him subsequently swallow a decoction of *nux vomica*. The animal expired as quickly as if the thoracic duct had been untouched. But here there is an objection again to the value of this experiment, as it bears on the question at issue. It is this,—that the simple impression of poisonous substances on the nerves of a part, will as certainly endanger the life of an animal, as though they had been introduced into the circulation itself. The learned Müller contends that the nerves are unable of themselves to take cognizance of poisonous agents, and that it is necessary the blood should directly receive them, in order that death may ensue. But the experiments of Brodie are decisive in disproving this latter position; and are forcibly calculated to convince us of the existence of such an influence. But Müller is more happy when he seeks to invalidate the deductions derivable from the last experiment I have noticed. "Since the thoracic duct," he says, "has sometimes in animals communicated with veins, for instance, branches joining the vena *azygos*, as in the hog; and since even a right thoracic duct occasionally exists, while the absorbent vessels have frequent communications with one another, the application of a ligature to the thoracic duct cannot absolutely prevent the passage of the poisoned lymph into the blood. Dr. Bostock observes on this question, that "concerning the contents of the lacteals, we have no decided proof of these vessels containing any substance except the elements of the chyle; and that although extraneous bodies have been occasionally found in them in minute quantity, these cases must be regarded as exceptions to the general rule;" and "*exceptio probat regulam.*"

Whether, therefore, we agree with Hunter and Monro, and their disciples, that the lacteals and lymphatics are the immediate and only agents concerned in absorption, indiscriminately of liquids containing no nutritive matters in solution, as well as of those which do contri-

bute to nutrition; or with Magendie, and his school, that the veins are the principal channels of absorption for liquids contributing nothing to alimentation, certain it is, that the fluids of either class are ultimately carried into the circulation, and that having so arrived at a common channel, they each, in their turn, are concerned in increasing the volume of the blood that is already contained in the vessels.

Now, supposing this much to be admitted,—that fluids, how different soever they may be in nature and properties, are ultimately carried into the circulation, (and this position, I apprehend, will not be gainsaid) it must equally hold good, I think, that the quantum of blood originally circulating in the vessels will at the moment of absorption be much augmented, and the vessels themselves, in proportion, distended. But then, says Paris, "It has very truly been observed that in healthy bodies, or such as are without any obstruction of the excretions, an unusual distension of the vessels cannot be produced, or at least long subsist; for it is evident that such an increased quantity of water in the blood will immediately pass off by one or other of the excretions; this effect, however, in itself, renders the operation of aliments of signal service in the treatment of the disease." I entirely agree with the argument employed in the passage I have quoted, and will go to the full extent of this writer's hypothesis, in as far as it applies to the body in health, and where the excretions are actively in play; but I am at issue altogether with him when he contends for its application in disease. And I feel a conviction that fluids are continually administered then, where their withdrawal is urgently called for, though the "*sufferings of Tantalus*" be added to the disease; whilst I am ready to admit that the waste-pipes of the system, viz., the emunctories of the kidney, the exhalants of the skin and of the lungs, are outlets sufficiently great and sufficiently well provided during a state of health, for the superabundant liquid contained in the vessels. I contend that engorgement of the vascular system is a consequence of its continued absorption, where the powers are oppressed with inflammatory or febrile disease; for, under these morbid conditions of the body, a cessation or diminution of the excretions is a primary and immediate consequence. The kidneys

no longer consent to eliminate urine; the skin grows impermeable, perhaps even to insensible perspiration. The watery vapour from the lungs is proportionably diminished; whilst the exhalant vessels of the intestines are in their turn as obstinately constricted. The propriety then,—the wisdom of distending the already bloated vessels, is a question that hinges entirely on the establishment of this position—have liquids the power, when absorbed under such a state of the system, of reopening the outlets, and of reestablishing the excretion; or is their tendency rather to aggravate the mischief, without overcoming the obstruction? Dr. Paris contends that their administration is called for under such circumstances; that, in a word, they are decidedly diaphoretic and, that the withholding them in fever is even injurious. And he reminds us that Galen and Celsus, with the physicians of the middle ages, were in the habit of giving their patients cold water to solicit diaphoresis in fever. In fever of a mild and ephemeral type, a practice of this kind may have its advantages; and, indeed, I allow it often succeeds in destroying the spasm which Cullen believes to give rise to the phenomena which constitute their essence, or in overcoming whatsoever agency may be concerned in their production. But in fevers which are protracted for weeks, and where art is unable to increase the discharge of urine or of perspiration, I see no advantage from distending the blood-vessels to a point beyond that which they have already undergone. And in obstinate phlogistic diseases the same must apply, but with yet greater import. Were I to hazard the assumption, that inflammations and fevers of obstinate continuance are aggravated and kept up by the inordinate quantity of fluids which we are in the habit of allowing our patients for the alleviation of that thirst which is a constant and attendant symptom on these morbid conditions, I might be charged with erecting an hypothesis which no appreciable facts could support. But theories, nay systems, have been raised on less plausible pretensions. And in support of my argument, or in disproof of the value of such as might directly oppose it, I might contend that we have yet to be informed of the benefits which are said to arise in the particular cases under notice, from a persistence in the

practice which I decry; and, that if its supporters deny it to be injurious, they have at least not succeeded in establishing its merits.

Woolwich, April 14, 1840.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Pathological Observations on the Diseases of the Uterus. By ROBT. LEE, M.D. F.R.S., Physician to the British Lying-in Hospital, and Lecturer on Midwifery at St. George's Hospital. The coloured illustrations from original drawings by Mr. Perry. London: Churchill, 1840.

If this work be carried on as it has commenced, of which we have no reason to doubt, it will prove a magnificent contribution to medical science. The object is to illustrate malignant diseases of the uterus; fibrous, calcareous, and other tumors of the same viscus, as well as the effects of inflammation; and the various morbid conditions by which the organs are disturbed; the diseases of the ovaria, Fallopian tubes, and external uterine appendages; and lastly, the diseases of the gravid uterus and its contents.

The present part contains cases and depositions illustrative of malignant diseases of the uterus. Not fewer than forty-two cases are detailed in illustration, and the following conclusions drawn:—

“From these cases it will be seen that the fungoid tumor of the uterus, or cauliflower excrescence, scirrhus, carcinoma, and corroding ulcer, are merely different forms of the same malignant disease; that the morbid changes may commence in the mucous and muscular coats of the fundus and body of the uterus, though they are observed most frequently to begin in the orifice and cervix. It may be inferred, also, from these histories, that inflammation of the uterus does not give rise to cancer in any form; and that the progress of the disease to a fatal termination is never arrested by those remedies which subdue inflammation. Three of the individuals whose cases have been related were under thirty years of age, three between thirty and forty, sixteen from forty to

fifty, and fourteen from fifty to sixty. In ten cases there was either no pain whatever experienced in the uterus, or it was only a slight dull pain or sense of uneasiness within the pelvis. In the remaining cases the pain experienced was acute and lancinating, and extended to the sacrum, groins, and thighs, and other parts around the pelvis. Hemorrhage from the uterus, fœtid discharge of serum, mucus and pus mixed with blood from the vagina, and sickness at stomach, were the symptoms almost invariably present after ulceration had taken place. The hemorrhage from the uterus was most profuse, and the pain slightest, in the fungoid form of the disease.

"In the treatment of these cases, when the pain was severe; relief was occasionally obtained by leeches applied to the anus, hypogastrium, and groins, and cupping glasses to the sacrum. In no case was great benefit derived from the application of leeches to the os uteri. The frequent injection of tepid water into the vagina, decoction of poppies, solutions of opium, conium, lead, zinc, nitrate of silver, and chloride of soda, often diminished the fœtor of the discharge, and soothed the sufferings of the patients. The tepid hip-bath often afforded great relief; and the pain was frequently mitigated by friction with camphorated liniment and laudanum over the loins, lower part of the spine and sacrum, and the whole region of the uterus. The belladonna plaister over the sacrum was only useful in a few cases and for a short period. Excruciating pain was often diminished by an enema of laudanum, and a little warm milk or solution of starch. Solid opium, the liquor opii sedativus, the preparations of morphine, and the extract of hyoscyamus, were the most useful internal remedies.

"Neither the removal of the whole uterus by a surgical operation, nor the destruction of its orifice with caustic or other means, was considered justifiable in any case."

Four plates, executed in the first style of the art, are given in illustration.

MEDICAL GAZETTE.

Friday, May 22, 1840.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

LATE REPORT OF THE POOR-LAW COMMISSIONERS.

IN our recent article on this subject, we discussed some of the flimsy apologies put forth by the Poor-Law Commissioners. They feel that their proceedings are as repugnant to the good sense of the people of England, as they are subversive of the dictates of humanity; and they endeavour, therefore, to persuade their readers that, were it not for their labours, rent would be swallowed up by poor-rates, and that a voluntary subscription raised by the charitable threatens the existence of the new economical reformation! At present we purpose to say a word or two on their conduct towards the medical profession; but before doing so, we would mention one point more relating to our former observations.

Mr. Assistant-Commissioner Tufnell, writing to head-quarters, praises the Commissioners and himself for the Cato-like austeri-ty with which he and they resist any relaxation of their rules. The public outcry, he says, is constantly directed against the "supposed inconsiderate harshness" of the Commissioners; and their rigid sense of public duty is the only reason they do not yield to it. Why, what foolish buttering of the Commissioners is this! Does not every human being know that the diminution of the rates is the tenure by which the Commissioners hold their snug offices?—and that by yielding to the outcry, and thus increasing the rates, they might lose 3000*l.* a year a-piece? We are perfectly certain, moreover, that were it not for the "outcry,"

the Commissioners would be too happy to knock another million or two off the rates, and realize the dreams of the most frugal economists. Nothing can be easier, when humanity is put out of the question. You have only to refuse all out door relief, and make the workhouses a few shades more intolerable, and therefore still better tests of extreme destitution. If the poor grumble, then, as Dogberry says, it is flat perjury; but if persons who keep gigs and are respectable, should prate about charity, or the like, the answer is ever ready, that they do not understand "the principle of population!"

It is said that a Highland chief, when asked what was to become of the numerous families whom he had ejected from his estate, to make room for sheep-walks, answered, "Loch Duich is deep enough for them all*!"

Some persons (more, perhaps, than would openly avow it) like the Loch Duich method; others sympathize more or less with their fellow creatures; but we take it that the disbelief in the benevolent intentions of the Commissioners is universal among all thinking persons, whether they are philanthropists or belong to the economical school of the Laird in the story. The only approximation to benevolence which can be conceded to them by the most indulgent critic, is of a very spurious kind. They hope for a Malthusian heaven upon earth; a millennium of celibacy and labourers' clubs; when whole generations of starvation shall have forced our husbandmen into supernatural prudence, and charity shall experience its euthanasia for want of objects to benefit. If any one should think this picture too highly charged, and should credit the pretensions of the Commissioners to philanthropy of a better sort, he will be painfully convinced of the truth of our

accusation, by their conduct as to medical relief; and will be forced to confess that in this point, as in every other, their "goodness wears the sterner face of love."

The claims of poverty, combined with sickness, are so strong, that they have always been considered irresistible; and until the iron age of the economists, even the dullest and coldest of men allowed the right of disease to relief. The benevolent go much farther, and instead of merely allowing the claim, would give it greater effect, and for this purpose would amend the machinery of society whenever it is insufficient for the purpose. Now it is clear, that under the old Poor Law, the medical arrangements for the relief of the indigent were lamentably defective. The salaries of the parish surgeons were absurdly small, and as we cannot reckon upon the tendered services of a thousand Howards, their attendance was scanty likewise. Hence, as the Commissioners are constantly boasting with a brazen voice of their regard for the comforts of the poor, it would have been well had they seized this striking opportunity of benefiting their unhappy clients. They tell us that they have diminished the poor rates by more than two millions sterling per annum. Be it so; then why not add one-fortieth part of this sum to the salaries of those on whose zeal the poor so materially depend? Instead of this, we have seen the horrid system of tenders continued, and medical officers pitted against each other till they agreed to attend the poor for sums which would not pay for drugs. In some observations by the Council of the British Medical Association, printed in the report before us, it appears that the average expense of each case of sickness, for medicines, leeches, surgical instruments, &c., was 4s. 3½d. in fifty-five hospitals and dispensaries; while in eight counties, the average sum for each case of illness (as

* Alison on the Management of the Poor in Scotland, 2d edit. p. 61.

deduced from the salaries,) for drugs, leeches, journey, and medical and surgical skill, was 3s. 3½d.; and in the metropolitan districts, the average sum for medicines, medical attendance, and skill, was 1s. 5¼d. a case.

The Commissioners, however, far from wishing to raise the salaries of the Union surgeons, till the reward somewhat approached the labour, have often threatened to bring down lads from London, if the established practitioners of the place were not sufficiently "reasonable." Now, the only want of reason in the tenders of the surgeons, seems to us to lie in the singularly small sums for which they offer to undertake the most onerous duties. These offers clearly demonstrate that however sensible each surgeon may be individually, the profession wants that reasonable *esprit de corps*, without which it cannot resist the attacks of a central despotism like that of the Poor Law Commissioners. No man has courage to ask for a fifth of the merited salary, when he knows that there is no tacit understanding to restrain other practitioners from offering to do the work for a tenth. Moreover, as parish surgeons always received salaries that were merely nominal, they have never ventured to raise their expectations to any adequate remuneration; the oppressed are satisfied with half justice, as he who has been accustomed to the rule of a miser sees liberality in the most frugal house-keeping. When Morton, in *Old Mortality*, returns after his long exile, Alice supposes that he will be "for keeping rather a mair house than puir auld Milnwood that's gane; and, indeed, I would approve o' your eating butcher-meat, maybe, as often as three times a-week—it keeps the wind out o' the stamack."

The Commissioners, however, are amply satisfied if the medical officers have butcher meat once a-week. As for keeping "the wind out o' the stamack,"

they reply, that they do not care to furnish the profession with carminatives—that is the doctors' look-out!

On the 21st February, 1830, the Commissioners addressed a series of questions to their assistants respecting the arrangements for affording medical relief to sick paupers, and their answers are given in the present report.

Among other things, they asked, whether dissatisfaction had arisen in any of the Unions as to the remuneration of the medical officers? To this Mr. Adey, assistant Commissioner for parts of Somerset, Gloucester, and Wilts, answers, "Yes; in fourteen Unions, on the parts of the medical officer."

Colonel A'Court answers for the counties of Southampton, Dorset, and Wilts, that "as well-qualified candidates are seldom wanting for any vacant appointment, I presume that the present salaries of the medical officers are considered reasonable; at the same time, I have often heard complaints as to the smallness of them."

Mr. Power, who is the satrap of Lancashire, and the West Riding of York, tells us, that, "in the Chorlton Union, the out-door medical relief is conducted by two medical officers at 5s. per case; and the total amount in this Union for one year has been £8. 12s. 10d.; which, added to their salaries for attending the two Union workhouses, gives a total amount of about £120 per annum."

The salaries of these two gentlemen, for attending the workhouses, are, therefore, about £30 a-year, or 1s. 8d. a-day, each: we hope that they rank among the "reasonable" ones.

Before we conclude this subject for the present week, we will just observe, that we must not assume that the surgeons are contented in those districts where no audible murmurs are heard. An ordinary knowledge of human nature will convince the inquirer, that oppression often derives its sharpest sting

from the danger of complaint; and this general rule was exemplified in the investigations of the Provincial Association, who found too many country practitioners afraid of denouncing the boards which ground them down. In such places one might rather expect to find a grim satisfaction expressed by those surgeons who had gained the suffrages of their masters, the Guardians, together with the privilege of supplying drugs to the poor out of their own pockets. It is thus that in those kingdoms, where even the shadow of freedom does not exist, and where argument is answered by the dungeon, the eternal cry is, "our father, the Emperor!"

PROGRESS OF CHOLERA.

DR. GRAVES has published in the Dublin Journal of Medical Science, a most interesting set of tables, illustrating the course and progress of cholera in this country. We regret very much that from their length it is impossible for us to transcribe them into our pages, but we are desirous that our readers should at least know where to find them (viz. Dublin Journal, March 1840). It is to Sir James Clark that the profession is indebted for these very important documents: it appears that, but for his exertions, they would never have seen the light. Dr. Graves observes, "These tables are taken from the official report presented by the Commissioners to William the Fourth, of which report but one copy existed; that copy was mislaid, and would have been lost to the world, had not Sir James Clark exerted himself to make it out, and by the aid of the Royal Librarian, it was at last found buried amongst an heterogeneous mass of papers in a drawer."

ROYAL MEDICO-CHIRURGICAL SOCIETY.

May 12th, 1840.

THE PRESIDENT IN THE CHAIR.

On Aneurisms, and especially Spontaneous Varicose Aneurisms of the Ascending Aorta and Sinuses of Valsalva, with Cases. By JOHN THURNAM.

AFTER some observations on the probable course and termination of aneurisms

limited to the lesser aortic sinuses of Val'salva, the author proceeded to the proper subject of his paper, on *spontaneous varicose aneurism of the aorta*, a form of disease which is new to pathologists. This lesion he stated to have been entirely overlooked by M. Breschet in his valuable memoir on varicose aneurism, although Mr. Syme had already detailed a case seated in the abdominal aorta and cava. After adverting to the interesting case published by Mr. Perry, in the 20th vol. of the Transactions of this Society, the author proceeded to the consideration of the lesion as occurring in the ascending aorta. He considered this part of the arterial system, including the aortic sinuses, as more liable than any other to the formation of such spontaneous intervacular communications, in consequence, principally, of its close contact with various parts of the venous system. He detailed eleven cases, and referred to the preparations from six others, in which spontaneous varicose aneurism had existed. Of these, two were seated in the descending aorta and inferior vena cava, and one in the arteria innominata and superior vena cava. The others were all seated in the ascending aorta (excepting one in the arch), and communicated, one with the superior vena cava, two with the right auricle, one with the right ventricle, and ten with the pulmonary artery.

He then proceeded to give the history of the disease, which he founded upon an analysis and comparison of these cases. He stated that the mode of communication between the aneurismal sacs and the venous system might occur in two principal ways, viz., either suddenly, and by rupture, in consequence of some effort on the part of the patient, or in a more slow and insidious way, by softening or ulceration of the walls of the sac. The symptoms which announce the formation of the varicose aneurism, under the first of these circumstances, were described, and were stated to resemble those of a rupture of the heart. The symptoms of the disease were divided into those connected, firstly, with the external surface and system generally; secondly, with the respiration; and, thirdly, with the state of the heart and great vessels. The most important of the general diagnostic signs were stated to be livor of the surface, or a distended and even varicose condition of the subcutaneous and other veins; severe and rapidly advancing anasarca: all these symptoms being limited to such portions of the body as are below, or the venous system of which is distal to the varicose orifice. When the varicose aneurism is between the descending aorta and inferior cava, the legs, scrotum, and lower half of the body, when between the ascending aorta

and the superior cava, the arms, face, and upper half of the body, and when between the ascending aorta, and one of the right cavities of the heart, or the pulmonary artery, the whole of the body, is the seat of the dropsical effusion. The dyspnoea is usually severe, and often attended by cough and bloody expectoration. The pulse is remarkably jerking, and there are, frequently, great emaciation, debility, loss of muscular power, and deficient animal heat, with sensorial disturbance, in the shape of delirium or coma. The physical signs were stated to be "a superficial, harsh, and peculiarly intense sawing or blowing sound, accompanied by an equally marked purring tremor, heard over the varicose orifice, and in the current of the circulation beyond it: this sound is continuous, but is loudest during the systole, less loud during the diastole, and still less so during the interval. The characters of the sound, as regards intensity and continuousness, will probably altogether distinguish it from any that is heard in ordinary cases of aneurism, or in valvular diseases of the heart."

The author then entered upon the consideration of the pathology, prognosis, and treatment of the lesion, including the rationale of the physical signs.

He also drew an interesting parallel between the symptoms of internal spontaneous varicose aneurisms, as developed in his paper, and those of the ordinary external or traumatic varicose aneurisms, as described by Hunter, Cleghorn, Scarpa, and Breschet.

The paper was concluded by some observations on aneurisms of the ascending aorta rupturing into the left cavities of the heart, and two illustrative cases were narrated.

PATHOLOGICAL DEPARTMENT.

DR. CLENDINNING IN THE CHAIR.

May 19, 1840.

Hydatids of the Uterus.

MR. NORTH exhibited a large quantity of hydatids recently expelled from the uterus, of a patient under his care. They consisted of a numerous collection of small-sized cysts, like small grapes or currants, attached together by pedicles, or floating loosely in a bloody-coloured fluid. The lady was presumed to be between the fourth and fifth month of her pregnancy. Previous to their expulsion, she had slight attacks of hæmorrhage, and occasional discharges of a watery fluid from the uterus.

After making some remarks as to the unfitness of the term *hydatid*, usually applied to these bodies, to designate their true character, Mr. North proceeded to ob-

serve, that, by all the best pathologists of the present day, it was agreed that they were a form of blighted or diseased ovum: that they were the result of a morbid change in the chorion. It appeared that these uniform cysts, clustered together like currants, were an enlarged or exaggerated condition of the small cysts attached by pedicles, which form the principal structure of the fleecy chorion, in the natural ovum. That such opinion is well founded, seemed to be proved by a series of about six preparations, which he had brought for the inspection of the members. These were aborted ova, in different stages of disease resembling that of the specimen on the table. In some of these preparations the chorion retained, in certain places, very nearly what we should allow was the natural structure of that membrane; while, in different parts of the same specimens, distinct appearances of the disease in question were manifest. A gradual conversion of the membrane, from its normal condition, to the diseased state presented in the specimen which he had just obtained, could be observed in the series of preparations.

Having offered some observations, in the next place, on the opinions commonly entertained as to the origin of this disease of the ovum, and as to the symptoms indicating its occurrence, as well as to the prognosis, he proposed the question to the Society—Whether the same kind of cysts or hydatids were ever expelled from the virgin uterus; in other words, whether this disease invariably depended or not on the presence of an ovum in the uterus? He knew that authorities of the highest name had declared that no authentic cases were on record, of a similar set of bodies being discharged by females, in whom there might not be well-founded suspicions of their having been pregnant. He himself, however, was acquainted with two cases, originally published in a Glasgow journal, by Dr. Andrews, where, from the facts detailed, he had no doubt that the cysts which were expelled were exactly of the same nature as those in the preparations on the table; and the females—young unmarried girls, in a respectable sphere of life—were altogether free from the suspicion of their having become pregnant. He put it to the Society whether there was any morbid condition of the uterus, independent of impregnation, by which the discharge of such hydatids could be satisfactorily accounted for. He was aware, and it was a point of importance to remember, that if, after delivery, a portion of the placenta remained adherent to the uterus, a change might take place in the structure of that fragment; so that in process of time, a disease of the nature at

present under discussion might be generated from it; and accordingly a female—for example, a widow—might have a discharge of such hydatids from the womb without any fresh impregnation. But in a medico-legal point of view, as well as for other obvious reasons, it was important to determine whether the hydatids referred to were ever found in a uterus where conception had not taken place; and that question he begged to put to the members of the Society.

Mr. E. Wilson was of opinion that the particular disease under discussion was invariably the production of an impregnated ovum morbidly affected. He stated his belief, although he was not prepared to give proofs of his views, that, in virgins, ova frequently escaped from the vesicles of De Graaff, and were conveyed along the Fallopian tubes to the interior of the uterus. But such ova were never matured—never had a chorion investing them. The formation of this membrane could only occur as a consequence of impregnation; and as the production of the so-called hydatids depended, in his opinion, on the presence of the chorion, he regarded the existence of the disease as certain evidence of previous conception.

Dr. Hodgkin coincided with the last speaker in considering that the cluster of cysts, very erroneously and absurdly regarded by some as entozoa, and hence termed hydatids, were always to be traced to the previous existence of an impregnated ovum within the uterus. The fœtus was seldom or never to be detected. Hence, if we pleased, in order to relieve the minds of friends, when doubts gave rise to uneasiness, we might say that this evidence was wanting to establish the fact of conception: and yet how the fœtus, in such a morbid condition of the chorion, should not undergo its proper development, and should not be recognizable in the discharged mass, we cannot be at a difficulty to understand. He had frequently, and for many years back, examined the appearance of the cysts in question, with particular care, and he was convinced that they were degenerated vessels of the chorion, a peculiar form of dilated vessels, the trunks and ramifications of which were more or less visible in different stages of the disease; and served to connect the cysts together in their characteristic clustered form. He did not altogether agree with Mr. E. Wilson, in supposing that ova could be transmitted, in the virgin, from the ovaries to the cavity of the uterus, or that they were conveyed along the Fallopian tubes. He did not doubt that the vesicles of De Graaff were frequently ruptured in virgin females; but as to what took place, in such occurrences, afterwards,

he did not venture, from want of evidence, to express any opinion.

Two cases of Tumors situated between the Cerebellum and Pons Varolii; and compressing these parts.

Mr. Shaw exhibited two specimens, obtained from different patients, of tumors lodged in corresponding situations at the base of the skull, and in neither case had any distinct cerebral symptoms been manifested during life.

The first specimen was removed from a female, 69 years of age, brought into the dissecting room of the Middlesex Hospital School, during the past session. The required certificate of the medical attendant attested that she had died of asthma. On turning out the brain, for the purpose of dissection, a tumor somewhat larger than a pigeon's egg was found lodged between the right lobe of the cerebellum and the inferior part of the pons varolii. One third of the tumor was imbedded in the part corresponding in situation with the crus cerebelli, while the remaining two-thirds projected above the level of the cerebellum. A considerable indentation was formed, for the lodgment of the lateral part of the tumor, in the side of the pons varolii. A lobe of the tumor, of the size of the point of the thumb, was also found fitting into a corresponding depression, or excavation, in the petrous portion of the temporal bone. The preparation of the temporal bone, containing this deep sulcus for the reception of a part of the tumor, was exhibited by Mr. Shaw, and it was seen to have been formed in the situation of the foramen auditorium internum. The margins of this foramen were absorbed to some extent around; so that the interior of the cochlea was disclosed to view, and the canal for the transmission of the portio dura was seen commencing near the hiatus Fallopii, on the anterior aspect of the bone. Notwithstanding there was this extensive removal of densely formed bone, there were no indications of disease in the immediately adjoining parts: a thin membrane, continuous with the dura mater, covered the surface of the depression, and the lobe of the tumor, although inserted into the sulcus, did not adhere to its bottom; but, on the contrary, was easily turned out from it. It was particularly observed that all the structures surrounding the tumor presented a perfectly natural appearance; that is, no adhesions were contracted; there was no opacity of the membranes, and, on the whole, there were no indications of the presence of the tumor having given rise to inflammatory action.

The only nerves which were directly affected in their course by the tumor,

were the *portio mollis*, and *portio dura* of the seventh pair. In regard to the former, no trace of it could be discovered; and it was inferred that it was totally destroyed. In reference to the *portio dura*, this nerve was seen taking its course over the surface of the tumor, and mounting upon its most prominent part. It was closely adherent to the investing membrane of the tumor, and was spread in a flattened, ribbon-like form upon it. Its fibrils retained the white pearly lustre which characterizes the nerves at their origins.

Being curious, from finding these appearances, to ascertain more precisely the condition of the patient during life, Mr. Shaw visited the surgeon of the infirmary where she died. He learned that the woman had been long an inmate of the workhouse; but that there were no symptoms which the medical gentleman could ascribe to cerebral affection. She had been bedridden for some time, but could nevertheless walk when required to get out of bed. She had no paralysis, had not been subject to fits of any kind, and her intellects were not perceptibly impaired. Particular inquiries were made as to whether the muscles of her face were paralysed; but it was stated that no defect of motion had been observed in them. This statement corresponded with the appearance of the face in the dead body, which did not exhibit any signs of distortion, or of the inflammation in the conjunctiva of the eye, so common in cases of paralysis from disease of the *portio dura*. The muscles also, whose action is controlled by this nerve, were found on dissection to present the usual red fleshy appearance of muscles possessed of their natural powers, instead of having the white blanched appearance which distinguishes muscles deprived of their action for some time.

The second specimen was taken from a lady, whom Mr. Shaw had frequent opportunities of seeing during her lifetime. The tumor in this case was also about the size of a pigeon's egg. It was situated upon the *crus cerebelli*, to which it was attached by a narrow base; and it had formed a considerable indentation upon the side of the *pons varolii*, to which it was also slightly adherent. It contained within it a fluid of the colour of urine, the walls being composed of a substance in point of consistence between membrane and medullary matter, and possessing considerable thickness. In this patient there were no symptoms, till within a few days of her death, of any general cerebral affection, such as stupor, paralysis, or convulsions. But she suffered intense and constant pain in all the surfaces of the head, and, moreover, was deprived of the sense of touch, in the same parts where the pain

was experienced. The cause of this acute pain, and want of sense to impressions, is to be understood when we observe that the fifth pair was completely involved in the substance of the tumor. The disease has had the effect of insulating the sensitive surfaces of the head, supplied by the fifth nerve, from the sensorium; while, by the irritation which the tumor produced, painful sensations, referrible to the parts supplied by the nerve, were experienced at the same time.

Dr. Williams observed, that the cases just related by Mr. Shaw offered striking illustrations of the extent of change which the brain might sometimes undergo in its most important parts, when that change was effected gradually. From the appearance of the tumors there can be no doubt that they were slow in their growth, and had been unattended in their development with inflammatory action. He had of late enjoyed several opportunities of witnessing changes of a remarkable extent in the substance of the brain, where the symptoms of disease had been most obscure, if not totally absent. One of the cases he shortly related. It was that of a man who, eight years before his death, had suffered from fracture of the skull, with depression, but who had recovered. He was subsequently seized with paraplegia, from the complicated effects of which he died. Upon examination of the brain there was a very considerable depression of a part of one of the hemispheres, at the seat of the fracture. It was also found that in various distinct parts ramollissement had taken place. Another appearance presented itself, which he had particularly noticed, but which he had not seen described in any works on pathology; that is, upon lifting up the *pia mater* from the surface of the convolutions of the brain, at the seat of the fracture, he found that a thin scale or layer of the cineritious matter could easily be lifted up along with the membrane; and on minutely inspecting the surface from which this layer had been detached, it presented a smooth and even appearance. To proceed with the account of the dissection: not feeling satisfied that the paralysis of the lower extremities could be the result of the disease found in the brain, especially considering that all the superior parts of the body retained their functions properly, he next examined the spinal marrow with care. It was found that this part presented a healthy appearance, except about a hand's breadth above the commencement of the *cauda equina*; here, upon one of the roots of the nerves, a small hard body, like a ganglion, was discovered, and in close connection with this gangliiform growth, a dense

body, like a fibrinous clot, and of the size of a bean, pressing upon the anterior column of the spinal cord, was found.

Mr. Shaw observed, that the remarks made by Dr. Williams were interesting, as they corresponded so exactly with observations made on a previous evening, when tumors of a large growth, compressing the substance of the brain, were exhibited before the society. He had brought, for the inspection of the members, a preparation which, he considered, showed, in a very remarkable manner, how great a change may be produced in a part of the brain, distinguished above all others for its importance in regulating the vital actions of the frame, and that part, notwithstanding the change, still retaining its functions. There is no portion of the central organs of the nervous system, upon which all the actions important for preserving life so directly and immediately depend, as the medulla oblongata, or that part where the spinal marrow is united to the columns prolonged from the brain; that is, at the foramen magnum, and arches of the atlas and dentata, the two first vertebræ of the neck. Here, if we wish to destroy life instantaneously in an animal, we introduce the knife, and all motion is at once arrested; the animal dying without a struggle, or even a heave of the chest. In this preparation it may be seen what a surprising change has been produced in the relative position to each other, of the occipital bone and the superior vertebræ of the neck, which surround and protect the part of the nervous system here referred to. Anchylosis has taken place between the articulating surfaces of the occipital bone and the atlas and dentata respectively, and, besides that, the bones have been displaced, previous to their union, in such a manner, that the greatest degree of distortion has been the consequence. The spinal canal has consequently been completely altered in its form, so that in place of its easily admitting the points of two or three fingers at its commencement, which would have marked its natural condition, it is with difficulty that a common pencil-case can be passed through it in any part.

He could not communicate many particulars regarding the patient from whom this specimen was taken; yet those with which he was acquainted were sufficient to show, that the man had survived the occurrence of the changes alluded to for some time. The preparation was obtained, some years ago, from a man, who had been picked up in one of the streets in the neighbourhood, in the middle of the night, in a state of insensibility, and who was brought by policemen to the Middlesex Hospital, no one being able to give an account of the accident. He died soon after his ad-

mission. Upon examining the brain, a fracture was discovered at the base of the skull, surrounding the foramen magnum, at some little distance from its margin, and presenting several angular points in the course of the fissure, some of which points had pierced the base of the brain. From the firm, consolidated appearance of the anchylosis, and the general aspect of the preserved bones, it is manifest that the disease which gave rise to the displacement must have been long completely cured; and it is to be presumed, from the circumstances in which the patient was found before his death, that he had the power of moving about without assistance.

Mr. E. Wilson stated, in reference to the observations by Dr. Williams, as to a thin layer of the cineritious substance of the brain being easily separable, in some cases, from that beneath it, that on making a post-mortem examination recently at Hanwell, of a patient who died insane, he had made a similar observation; and in drawing the attention of Dr. Conolly, the physician of the establishment, to the fact, that gentleman had stated that it was an appearance which he had seen in several patients, the subjects of insanity.

Dr. Hodgkin observed, that the appearance referred to had not escaped his notice; and he believed it had been described by authors. He related some particulars of a case in which a tumor of large dimensions was found imbedded in the substance of the brain.

Fibrinous clot in the arch of the Aorta.

Dr. Clendinning, at the close of the meeting, begged to exhibit a specimen, in which a clot of blood was seen plugging the termination of the arch of the aorta. He introduced the specimen chiefly for the purpose of stating, that in the interior of the fibrinous accumulation, a fluid, possessing all the common appearances of pus, had been observed occupying a distinct cavity.

Mr. Gulliver observed, that the fluid resembling pus, referred to by Dr. Clendinning, was altogether of a different nature from pus; both chemically and microscopically this difference could be established. The fluid in question has a greater tendency than pus to submit to the putrefactive process, and does not form the same compounds with alkalis which pus so readily forms. Again, examined under the microscope, it is seen to contain numerous minute granules, not perceived in pus, and only a tenth of the size of the pus globules. When put between thin plates of glass, it does not give rise to the iridescence displayed by pus in similar circumstances. The importance of this distinction, in re-

ference to theories at present much in vogue, concerning the supposed effects of absorption of pus, or the circulation of pus in the blood, he illustrated by several interesting observations which he had recently made.

—
To the Editor of the Medical Gazette.

SIR,

IN your report of the last Pathological Meeting of the Medical and Chirurgical Society, you have omitted to state—what I mentioned at the time—that the three cases which I read an account of, occurred in the practice of Mr. R. F. King, of Whitehaven, who had transmitted them to the President to be laid before the society.

I am, sir,

Your obedient servant,

CHARLES HAWKINS.

Great Ryder Street,
May 11th, 1840.

ASSOCIATION OF PHYSICIANS, DUBLIN.

May 4th, 1840.

DR. HUDSON in the Chair.

Murder by Drowning.

THE secretary, Dr. Thomas Brady, said he wished to lay before the association an account of a trial which had taken place at the late assizes of Gloucester, and which presented some interesting features in a medico-legal point of view. It was the case of a woman convicted of the murder of her infant child by drowning it; upon circumstantial evidence, of which the medical proofs formed the most important link in the chain. An account of the trial had appeared in the newspapers; but in it the testimony of the medical witness was entirely misrepresented—indeed, it was this misrepresentation that had drawn his attention to the case. The following, from the London Morning Herald, April 8th, gives the general facts with sufficient accuracy:—

“Celia, the wife of John Tippins, was charged with the wilful murder of her male child, aged five weeks, by drowning it.

“It appeared that the prisoner had left Hereford on foot, at the end of October, to walk to Bristol, to join her husband, whom she stated to be a painter and stenciller; and that, on the afternoon of Saturday, the 2d of November, she arrived at the White Lion, at Cambridge, in Gloucestershire, which is twenty-three miles from Bristol, the child being then with her; and that at six o'clock on the same evening she arrived at a lodging-house at Newport, in

Gloucestershire, which is five miles nearer Bristol, she then having no child with her. It further appeared, that at nine o'clock on the morning of Sunday, the 3d of November, the body of a child, which had no clothes on, except one sock, was found in a water-course which runs under the turnpike road from Cambridge to Newport, at about a mile from the former place. The body was examined by Mr. Warner, a surgeon, residing at Dursley, on the Monday, who then gave it as his opinion (without dissection) that the child died from drowning, and afterwards on Wednesday examined it, but found no traces of disease about it; but from finding that the mouth and lungs were filled with frothy mucus, and that the lungs bled freely on being wounded, he gave it as his opinion that the child had died of drowning. It was further proved, that, on the following Tuesday, the prisoner was apprehended at her husband's house in Bristol, where a bundle of child's clothes, very wet, was found; but it was also proved, that when the prisoner was taken to Cambridge, at the time of the inquest, she was asked if the child was her's, and she said it was; and that on Mrs. Ludlow, the landlady of the White Lion, asking her how she came to do it, she said she did not know; and on Mrs. Ludlow saying, ‘I suppose you would have given the world to have the child alive again,’ she replied, ‘I would.’ It further appeared that the prisoner had registered the birth of this child with one of the registrars of births at Bristol, as the child of herself and Thomas Lee.

“Mr. Godson cross-examined the surgeon at great length, who said, if a child were brought to him in a room, without a word being said that it was drowned, that he could, from external appearances, say whether it was drowned or not. He added, that almost all the symptoms which he observed were the same as if the child had died from convulsions. He also added, that, according to Dr. Beck, the sign of drowning by an appearance of the same fluid as that in which the body was found was not one of the best *criteria* whereby to form judgment.”

To this report it is only necessary to add, that the child was the fruit of an adulterous intercourse with Lec, in whose house, in Hereford, she had been employed as wet-nurse; that her husband had consented to receive her on condition that the child was supported elsewhere; that she had been to Hereford to try and induce Lee to provide for it—had been brutally spurned by him from his door, and was returning on foot and in great distress with the child to Bristol.

On reading the above report, he, Dr. Brady, wrote to the medical witness, Mr.

Warner, expressing his conviction that his opinions, as to the signs of death from drowning, must be greatly misrepresented in the *Herald*, and requesting to know upon what signs in this case he had relied as proofs that the child had been drowned. That gentleman has politely favoured him with a very full communication on the subject, from which he was able to present to the association an accurate account of the appearances in the dead body upon which he founded his opinion. He never asserted as was falsely reported in the *Herald*, that he could determine whether a person had died of drowning or not from an external examination of the body. On the contrary, he distinctly stated that this was impossible. When he first saw the body, November 4th, it presented the following appearance:—"The skin was remarkably pale; there were wet leaves and weeds in the hollows, as the arm-pits, groins, &c.; the face was considerably swollen; the tongue forced to the front part of the mouth, rendering the lips and parts thereabout prominent, amounting to distortion. There were no marks whatever of external violence—no wasting of the body. On the contrary, it appeared a fine strong male child." The autopsy did not take place till the 6th. "The swelling of the face had completely subsided, and the face bore now a natural appearance. In the abdomen the organs were found quite healthy; the stomach contained about two ounces of fluid of the appearance of milk partly converted into chyle; he could not say whether there was water mixed with it. On opening the chest, the thymus gland was found of considerable size, but apparently not diseased; the lungs of a natural colour, in a state of partial inspiration, and bled very freely on being cut into. The air-cells contained some frothy mucus, as did also the extremities of the bronchial tubes. The blood was remarkably fluid."

From these signs taken collectively, and from the absence of any appearance in the dead body to indicate natural death, Mr. Warner concluded the child had been drowned.

The woman was found guilty, and sentenced to death, but the punishment has been commuted to transportation for life.

Concurrence of Empyema and Phlegmasia dolens.

Dr. Law detailed a case of pleuro-pneumonia of the right side, in a young woman, aged 22. The symptoms were very urgent. The treatment consisted in general and local bleeding, and the exhibition of mercury. Four and twenty grains of calomel produced salivation. The case was progressing towards recovery, when the patient got up and exposed herself to cold; in

consequence of which she was seized with sharp lancinating pain in the left side. Leeches, largely applied, removed the pain; but, on examination, it was found that effusion had taken place into the cavity of the pleura. A blister was applied to the side, and, the effects of the mercury which she had already taken having passed away, it was directed to be dressed with mercurial ointment. She was ordered, besides, *Pil. hydrargyri c. ipecacuanhâ*. This treatment having been continued for a few days, the pleuritic effusion disappeared. She had now a profuse expectoration of whitish frothy mucus, in fact bronchorrœa, and, in the postero-inferior left lung, there was a large loose muco-crepitating râle, while the respiration elsewhere was quite natural. Pills composed of sulphate of zinc and opium, and inhalation of hot water and vinegar, were ordered, with the view of checking the profuse expectoration, and succeeded in doing so to a certain extent. It, however, soon became as abundant as ever, and began to emit a peculiar sickly smell, which, after a short time, became fetid, but not so decidedly so as to make it certain that the fœtor depended on gangrene of the lung. About this time the patient began to complain of pain in the calf of the left leg, which, to the eye, was neither red nor swollen. A stimulating liniment relieved it. The fœtor, not only of the expectoration (which was of a greenish purulent character), but also of the breath, was now very marked. In the postero-inferior left side, there was dulness on percussion, and there was to be heard a large mucous râle, almost amounting to gargouillement. She was ordered a mucilaginous mixture, to which was added a drachm of the solution of the chloride of sodium, with a view of correcting the fœtor of the expectoration and of the breath. On the 24th of January, when she had been a month in hospital, she was seized at night with a severe sharp pain in the left thigh, which deprived her of all power of motion of the limb. The next morning the entire leg and thigh were very much swollen, of a dark pale colour, and marked with blue veins. The limb, when pressed superficially, felt elastic, and did not pit; but when stronger pressure was made, it conveyed the sensation as if the deeper-seated parts had not the same density as the superficial. Her chief pain she referred to the groin. The inguinal glands were not unusually developed. The pulse was 140 in the minute, sharp, and hard. Thirty leeches were directed to be applied to the groin, the limb to be stuped, and pills of two grains of calomel and half a grain of opium to be taken every third hour. The leeches relieved the pain in the groin, but she still complained of considerable soreness

when pressure was made along the course of the femoral and popliteal vessels. The temperature of the limb was much greater than natural; pulse 130, full, but compressible; the abdomen was tympanitic; thirst. Forty leeches were directed to be applied to the most painful parts of the limb; stupor afterwards; and the pills of calomel and opium to be continued. She was very weak after the application of the leeches, and her stomach became very irritable; a little wine, however, revived her. There was no pain now in pressing the limb any where; the swelling was still very considerable, but it did not retain its uniform elasticity, being cedematous in parts; it continued to exhibit its white glazed appearance: the pulse was now 126 in the minute, short, and rather hard; the systole of the ventricle short, rapid, and attended with impulse. The cough was now lost sight of, and not because the affection of the limb had caused it to be overlooked, but because that since the limb had become affected, it had really become so much less that she felt very little inconvenience from it. She continued to take the pills of calomel and opium, and had now taken forty-six grains of calomel, without the gums being even soft or swollen.

The report on the 30th was,—pulse 120; heart's action sharp and quick (irritable); she had slight muttering delirium during the night; cough has quite disappeared; pills of calomel and opium directed to be continued, as also porter and beef-tea which she had been taking.

31st.—Swelling of limb much diminished; cough has returned; sputa tough, viscid, green, purulent; percussion yields a clear sound in both sides of the chest anteriorly, and in all posterior right, dull alone in inferior left; then there is a large mucous rale; abdomen tympanitic; heart's action more feeble. She feels extremely weak; pills to be continued. Let her have arrow-root, and four ounces of wine.

Feb. 2nd.—Pulse 120, small, and rather sharp; heart's action accompanied with considerable impulse, and heard extending through the chest; expectoration very fetid; the swelling of limb greatly lessened, and it has quite lost its shining glazed appearance. There is a peculiar yellowish pallidness of the face, with a glossiness of the eye like what is observed in puerperal fever. She has now taken 96 grains of calomel without any effect on the gums. The following pills were substituted:—

R. Chlorid. Calcii, gr. duostem; Extract. Opii agnosi, Pulv. Ipecacuanhæ, aa. gr. tria. Fiant, pilulæ quatuor, una tertiis horis sumenda.

She was ordered eight ounces of wine, and beef-tea.

3rd.—Cough more distressing, and sputa more fetid. She has diarrhœa. Pills of chloride of calcium to be discontinued, and to have instead five grains of Dover's powder every third hour.

4th.—Diarrhœa continues. Following mixture ordered.

R. Mist. Cretæ, ℥vi. Confect. Opii, Confect. Aromatic. aa. ʒj. Sa. ʒj. 3tiis. horis.

Should diarrhœa continue, the following enema to be administered:—

R. Decoct. Amyli, ℥vj.; Tinct. Opii, gtts. xx. Plumbi Acetat. gr. xii. Twelve ounces of wine.

Diarrhœa has ceased.

7th.—Pulse 140; cough troublesome; green, fetid, purulent sputa. She has had a good deal of delirium during the night. Stomach irritable, and bowels again relaxed; exhaustion very great.

Enema e Decoct. Amyli, Tinct. Opii, et Plumbi Acetat. to be repeated. Let her have chicken broth, and twelve ounces of wine.

Her condition now was extremely discouraging; her weakness was extreme; the least motion hurried her breathing. While things were in this state her mother came to her from Scotland; then a visible amendment took place in her; she begged of her mother to bring her back with her to Scotland, to which Dr. Law pretended that he would consent at the end of a week, scarcely expecting that she would be then alive. The rapid improvement which took place in her when she heard that she was to return home (for Scotland was her country), was most striking. The prospect seemed to communicate strength to her; and at the end of the week, she was carried from her bed to the Glasgow steamer, and thus conveyed to Scotland. Her recovery was slow, but complete.

The features of the case which appeared to Dr. Law to entitle it to notice were,—1st, the pulmonary affection in that stage of it when the evidence of effusion into the side having ceased, the profuse fetid expectoration succeeded. Dr. Law adverted to an interesting paper, by Dr. Green, in the last number of the Dublin Medical Journal, on Empyema. In it Dr. Green observes, how frequently a copious purulent expectoration, independent of a fistulous communication between a bronchial tube and the pleural cavity, or of a tubercular excavation, or of abscess, the effect of pneumonia, is present in empyema. He adopts a suggestion of Dr. Hutton's to explain it; that it is an effort of nature to relieve itself of the effusion, as if by a vicarious secretion. Dr. Law quite agreed with Dr. Green's explanation as applicable to some

cases, although not to all; for that he had met with three cases of unequivocal empyema, in each of which the patient had a distinct sensation of something giving way in the side, and immediately threw up a large quantity of green purulent matter; the breathing was at once relieved, and the side lost its dilated appearance. Dr. Law did not think it possible that Dr. Green's explanation could apply to such cases, although he confessed the difficulty of supposing, that the collection of matter, like an abscess, should make its way into the lung, and thus be expectorated, without the phenomena of pneumothorax succeeding. Yet, in the face of this difficulty, he preferred this explanation, which he conceived derived some countenance from what occurs when abscesses in the iliac fossa make their way into the intestine, there being no escape of fæces from the intestine. Dr. Law confessed that the analogy was not very exact.

The second interesting feature of the case was, the complication of phlegmasia dolens, which was the second instance of the kind which Dr. Law had met with; each proving, that this modification of disease is not necessarily connected with the puerperal state: for while the young woman, the subject of the present case, had never borne children, the subject of the other instance was a young man.

The third point of interest connected with the case, was its illustrating an observation made by Dr. Law, in a number of the Dublin Medical Journal, when remarking on the exhibition of mercury, how some diseases had the effect of rendering the system signally insensible to the operation of this medicine; for while, in the early stage of the disease, 24 grains of calomel produced salivation, when the phlegmasia dolens came on, and its use was again resorted to, 96 grains did not make the least impression. Dr. Law regarded the constitutional symptoms, exhibited at this stage of the disease, as exactly those which he had observed in almost all those diseases which he found to resist the use of mercury, such as puerperal fever, different modifications of constitutional irritation, &c. In the case in question, the varying susceptibility of the effects of the mercury could alone be attributed to the varying conditions of the system, the effects of disease.

The last point to which Dr. Law adverted was the extraordinary influence which the mind exercised over the body: "Posunt qui non posse videntur." Dr. Law noticed how the cough seemed to be suspended during the affection of the limb, and returned according as this affection gave way.

Dr. Aquila Smith gave an account of a case of pneumonia, in which delirium ap-

peared at the very commencement of the attack. The patient was a man of *temperate* habits. The disease yielded to an active mercurial treatment.

BOOKS RECEIVED FOR REVIEW.

On the Improvement and Preservation of the Female Figure: with a new Mode of Treatment of Lateral Curvature of the Spine. By G. B. Childs, Esq. M.R.C.S. &c. London, 1840. 12mo. pp. 188, with six Lithographic Plates.

On the Nature and Structural Characteristics of Cancer, and of those Morbid Growths which may be confounded with it. By J. Müller, M.D. Professor of Anatomy and Physiology in the University of Berlin, &c. &c. &c. Translated from the German, with Notes, by Charles West, M.D. Graduate in Medicine of the University of Berlin. Illustrated with numerous Steel Plates and Wood Engravings.

Hippopathology: a Systematic Treatise on the Disorders and Lamenesses of the Horse; with their Modern and most approved Methods of Cure; embracing the Doctrines of the English and French Veterinary Schools; the Opinions of the late Professor Coleman, Director Girard, Hurtrel d'Arboval, and other British and Foreign Veterinarians. By Wm. Percivall, M.R.C.S. Licentiate of the Company of Apothecaries, &c. &c. &c.

A Practical Treatise on the Diseases of the Eye, and their Treatment, Medically, Topically, and by Operation. By Frederick Tyrrell, Senior Surgeon to the Royal London Ophthalmic Hospital, &c. &c. 2 vols. 8vo.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF SURGERY.

Delivered at the Westminster Hospital School,

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary.

FRACTURES, *continued.*

The Sternum, Ribs, Costal Cartilages, Ossa Innominata—Scapula, its body, spine, inferior angle—Coracoid and Acromion processes—Neck—Clavicle—Humerus—Forearm—Radius.

THE STERNUM.

A FRACTURE of the sternum may be transverse or longitudinal, simple or compound: it is almost always produced by direct violence, a blow or a fall. In a man of 28, David saw the superior and inferior part separated from the middle, by a fall on the back. Chaussier saw a case, in which fracture was produced by the action of the sterno-mastoid and recti muscles, in the efforts made by a woman during parturition.

When the fracture is transverse there is usually displacement; the inferior fragment is pushed, as it were, a little in front of the superior. If there be comminution, the fragments frequently are driven into the anterior mediastinum. Direct fracture cannot be produced without a severe shock, and the thoracic viscera are generally injured; the displacements may excite inflammatory action, abscess of the mediastinum, and caries or necrosis of the sternum. Cases have occurred in which the displacement of fragments has been so great as to lacerate the heart.

Simple fracture of the sternum is not a dangerous accident: but, unfortunately, the chances of complication are so great, that it is often mortal. Ill reduced, Petit saw a case in which it was followed by dry cough, palpitations, and other inconveniences to the thoracic functions.

Treatment.—The treatment of cases of simple fracture is very simple. The patient lies on his back; the trunk is flexed, by placing pillows under the shoulders and the pelvis; the thorax may be surrounded by a belt, to induce diaphragmatic respiration, and to keep the parietes as quiet as possible. If either fragment project, moderate attempts may be made to reduce it, but no violence should be employed. If there be great displacement, the patient must be placed in such a position as will best relax the attached muscles, and facilitate the replacing of the fragments. Ordinary means failing, it has been recommended to place under the patient's back some cylindrical body, such as a barrel; "in this position, the recti and sterno-mastoid muscles would so drag upon the two extremities of the sternum, as to disengage the fragments." These failing, elevators might be used, or a fixed portion of the bone might be trepanned, so as to allow of the application of the necessary force. It is, of course, advisable, to reduce the fragments as nearly as possible. Should inflammatory action be impending or developed, active antiphlogistic means must be employed. If suppuration should take place, the means of procuring the evacuation of the pus were indicated when speaking of abscess.

RIBS.

In old people fracture of the ribs often happens, and usually more than one suffers at the same time. The middle are more frequently affected than the superior ribs, which are protected by the shoulder and the clavicle; the two inferior are so move-

able that they rarely suffer. The fracture commonly affects the middle part of the rib; but it may affect two points, so as constitute three fragments. A specimen was shewn at the Society of the School of Medicine at Paris, some years ago, where, in a woman of 79, the last four left ribs were each fractured at two points. Sometimes there is much, at others little displacement. It may result from direct injury, may succeed to an accident, by which a person is squeezed between a cart-wheel and a wall, for instance. In the *Med. Chir. Review*, Oct. 1833, is a case where the fracture happened during a fit of conghing. It was observed by Dr. Graves; the patient was a woman of 47, in good health, and presenting no indication of fragility. In the *MED. GAZETTE*, vol. 16th, are two similar cases by Mr. Naukivell.

Fractured ribs may be complicated, by injury to the pleura or the lung; by emphysema, pneumo-thorax, wound of intercostal artery, or laceration of the diaphragm. If there be no displacement, this accident is not very easily distinguished, especially in stout people. The hand must be placed either on the point where pain is felt, or that where the injury has been received; the patient is directed to cough, the ribs are moved, and crepitation may be felt. We may also be able to feel inequality, or a giving way at the point, if the finger is passed firmly along the rib. If you have found one fractured, do not search for more; the treatment is the same whether there be one or four, and you may spare your patient much unnecessary pain. Usually there is oppression, fever, painful cough, sometimes bloody expectoration. Emphysema is not an uncommon complication; it supposes destruction of the pleura, and of the surface of the lung.

It is evident that the danger of these fractures depends upon the complication. A fracture is more dangerous in an old than a middle-aged person; so is it in the superior than the inferior ribs. If the fragments are forced inwards, the case is more serious than the opposite condition.

Treatment.—Uncomplicated, the treatment is simple; the object is to preserve the walls of the chest as free from motion as possible. If there be no severe external injury, this may be done by surrounding the chest with a broad flannel or linen roller, or, what is better, a rib belt; in either case let it be so tightened as to prevent, as far as possible, transverse or upward movement of the ribs. If fragments be depressed, it has been recommended to apply thick compresses to the anterior and posterior extremities of the fractured rib, and to press strongly upon them by means of a belt or bandage, in the hope of reducing the displacement. I have never seen much good

derived from the plan; I have known evil to follow too much meddling. If there be symptoms of wounded lung, or inflammation of that organ, very large and repeated general and local bleedings are necessary. We must not wait the development of peripneumonia, but use every means to prevent it. Laxatives and antimonials must be administered; and if, after the energetic use of these agents, a painful and frequent cough continues, we may venture to let the patient sip some opiate, for the relief which is often thus obtained will more than counterbalance any injurious effect of the opium.

OSSA INNOMINATA.

Fracture of the bones of the pelvis is comparatively rare. This we might naturally expect from their situation and their solidity. To occasion fracture, the injury must be very severe, and directly applied; and too generally the viscera contained in the pelvis suffer. The *ilium* is, I believe, never fractured by indirect causes. I saw a case the other day, a child, in whom the crest was completely detached, being then in the condition of an epiphysis: but fractures of the crest, and of the middle portion of the ilium, are not usually accompanied by much displacement. Still there is a case mentioned by Sanson, where a square piece of the ilium, of the size of four fingers, was detached, and dragged up near to the thorax. When the anterior superior spine alone is detached, it has been found dragged downwards and forwards, by the sartorius and tensor vaginæ femoris. It is not always easy to ascertain the kind of injury which has been sustained, yet, if we relax the muscles, we shall usually be able to distinguish mobility, if not crepitation. Dupuytren thought that fracture of the left ilium always produced constipation.

Any portion of the *pubes* may be fractured, either by a fall from a height, or by being jammed between two unyielding bodies, or by a wheel passing over the trunk. Sir A. Cooper mentions cases of this kind, where there was a good deal of displacement; the detached fragments may compress or destroy the urethra, causing retention of urine, or urinary abscess. Desault extracted a fragment which had penetrated the urethra in a similar case, and for some years occasioned much suffering. Maret successfully removed the greater portion of the pubis, which was detached and displaced so as to compress the urethra and the vagina. The situation of the pubis is sufficiently superficial to render the diagnosis of such injuries comparatively easy.

Though rare, several cases of fracture of the *tuberosity of the ischium* are on record. In some of these cases there was very little displacement; in others, it was drawn down

by the muscles of the thigh, and no difficulty appears to have been experienced in detecting the kind of injury.

The fracture may implicate the *acetabulum*. Sir A. Cooper, Sanson, and others, have seen the three bones separated at their junction in this cavity. The fundus may also be driven in. Sir A. Cooper, Gama, and others, have seen the head of the femur forced through the cotyloid cavity into the pelvis, from a fall on the great trochanter. This species of accident is distinguished, according to Cooper, from luxation, by the mobility of the thigh, and by crepitation.

Free from all complication, these injuries are not very dangerous; but, unfortunately, they are generally accompanied by great contusion, ecchymosis, damage to pelvic viscera, or concussion of the spine; either of which materially increases the danger.

Treatment.—The treatment, of course, varies with the seat of the injury. The mode of reduction varies with the case. If we relax the muscles which tend to displace fragments, reduction is comparatively easy. Supposing the iliac spine, or other portion of the ilium, to be detached, the chest will be inclined toward the fractured side; to elude the action of the abdominal muscles, the thigh must be flexed, in the sense of abduction, or adduction, according as the fragment is drawn inwards or outwards. If this plan should not succeed, the displaced fragment may be reduced, by making tense the muscles of the affected side, by inclining the trunk to the healthy side. If the anterior superior spine be detached, the thigh must be flexed so as to relax the sartorius and tensor vaginæ femoris. During the whole treatment, the patient's position should be such as is proper for relaxing those muscles which may occasion displacement. The position which usually answers best is to lie on the back, to keep the thighs together, and to flex them upon the pelvis; for this purpose, a bandage should be placed around the knee, and a thick pillow in the ham. The same situation answers best in fracture of the pubis. In women we may facilitate reduction, by passing the finger into the vagina.

If the tuberosity of the ischium be detached, the patient must lie on the sound side, the thigh of the injured side extended, the leg flexed, and the fragment sustained by compresses and bandages.

If the fracture affect the cotyloid cavity, reduction is not always possible. If the limb be rotated inwards or outwards this may be remedied. All that can be done is to attend to the position of the limb: the most convenient is semi-flexion, upon a double-inclined plane; we shall thus prevent rotation, and relax the muscles. What-

ever be the fracture, perfect rest is essential. If there be infiltration of urine, free incisions will be necessary, and any inflammatory accidents which may supervene must be energetically treated by antiphlogistics. There is one remark which applies equally here, and to all the bones of the trunk—it is, that there is nothing more difficult than to induce the patient to preserve the necessary position.

SCAPULA.

This bone is so very moveable, and so well covered, that it is unfrequently fractured: there are, however, certain parts of it more projecting and less protected than others, which now and then suffer. Of these points the *acromion* is most frequently affected, commonly in consequence of a fall upon the shoulder; next comes the inferior angle, the spine, the coracoid process, and the neck, and they are almost always accompanied by considerable contusion, which is sometimes more serious even than the fracture itself.

When the *acromion* is the seat of fracture, the head is drawn towards the affected side, the arm remains immoveable at the side, and the patient feels a pain at the part, which is increased by every attempt to raise the arm: if, during these efforts, the hand be placed upon the *acromion*, we feel its summit giving way, and a crepitation produced. If left to itself, it will get well, but the fragment retains its vicious position, and the motion of the arm is constrained. Sometimes it is united by bone, but often by ligamentous matter, so as to cause an artificial joint.

Treatment.—The treatment of fracture of the *acromion* consists in raising the fragment to its proper height; this is done by raising the head of the humerus, and maintaining it in that position close to the side, and relaxing, as far as possible, the deltoid. If the patient have a narrow chest and prominent shoulder, it may be proper to place a compress in the axilla, so that the humerus shall be parallel to the axis of the body, but Sir A. Cooper doubts the necessity for the axillary pad.

If there be fracture of the *spine of the scapula*, its superficial situation frees the diagnosis from difficulty; the fragments are moveable, a pain is felt at the part during the action of the deltoid in raising the arm. It is usually accompanied by more contusion than the fracture of the *acromion*, but the reduction is easily accomplished, though the maintenance of exact coaptation is by no means easy: when reduced, small narrow splints of milled board should be placed above and below, but parallel to the spine, and fixed by a figure of eight bandage.

Simple fracture of the *inferior angle* is

usually easily detected, but it may be complicated. The producing cause, the local pain, the displacement of the inferior fragment in a direction varying with the muscle attached to it, whether it be the serratus alone or the serratus teres and latissimus, the crepitation which can always be produced, are signs which are sufficient to prevent any mistake in diagnosis. If the fracture be vertical, it is less easily detected, because there is no great displacement. In the treatment of transverse fracture, which above the spine is rare, we must seek to act on the inferior fragment, to bring it, as near as may be, in contact with the superior; this is best attained by bringing the elbow forward, and, if the patient can bear the inconvenience, passing the hand over the other shoulder and fixing it there. If it cannot be borne there is one satisfaction—the cure will still proceed, though with a little deformity, provided the parts be kept at rest.

The *coracoid process* is so well covered, and so well protected, that it is rarely fractured. The only case I know, verified by dissection, is that of Mr. South. When it has suffered, if there be no great contusion, the application of the finger upon the point should be sufficient to detect it; but, unfortunately, as it is not ruptured by muscular action, the violence is great, and the tumefaction so considerable as to defeat the attempt to ascertain the injury in this way. If the process be fairly detached, the action of the lesser pectoral, the biceps, and the coraco-brachialis, would tend to depress it, but this depression would be very considerable, first, because their fibres stretch along nearly to its base, and, secondly, because the coraco-acromion and coraco-clavicular ligaments would tend to maintain it *in situ*.

I know no other means of treatment applicable to these fractures than relaxing, as far as possible, the muscles which are attached to the process. The forearm should be semi-flexed and brought to the side, and secured there by bandage.

The *neck of the scapula* may be fractured at its base, but the accident is of very rare occurrence, and we can readily conceive the displacement which may occur in that case. The weight of the arm, and the long head of the biceps, will tend to drag down the glenoid fragment, and the teres, latissimus dorsi, and the lesser pectoral, would increase the displacement towards the axilla. However, the injury done to the soft parts in the production of this fracture is commonly so great, that much difficulty will be experienced in ascertaining the amount and kind of injury.

The symptoms of this fracture may impose upon a careless observer, and induce

him to suspect luxation of the humerus. In one and the other there is a hollow at the shoulder, the axis of the arm is oblique downwards and outwards, the elbow removed from the side; still there are differential signs which render mistake difficult. In fracture, reduction is easier than in luxation, but the displacement recurs as soon as the support is removed; this does not happen in luxation. If, after reduction, we grasp the shoulder, applying the index finger upon the coracoid process, which adheres to the glenoid fragment, and rotate the limb, crepitation will be readily perceived. The fracture causes a stiffness at the joint, which remains very long. To reduce it, we disengage the glenoid fragment from the axillary fossa by pushing the arm upwards and outwards; a pad must be placed in the axilla, the arm must be fixed across the chest, as in fractured clavicle, and the apparatus, according to Sir A. Cooper, should not be removed before the tenth or twelfth week in the adult.

CLAVICLE.

The situation, form, and texture of the clavicle, render it very liable to fracture, and it much more frequently happens from indirect than direct violence, from falls upon the shoulder or the elbow; under these circumstances the clavicle is pressed between two points, the shoulder and the sternum; its curvatures increase until its texture can no longer resist, and fracture is the usual consequence. Both clavicles may be fractured at the same time. A strong carman was squeezed between a high wheel and a wall, when this accident happened; he was cured on the thirty-second day. Another case of fracture of both clavicles is mentioned by Seutin.

Fracture by direct violence is very easily produced, particularly if the violence be directed upon a point near the middle of the bone, because both ends are supported, and the centre will give way. Some time ago I saw a case in which the fracture was produced by a blow of the sails of a wind-mill.

Although in a great number of cases the fracture is complete, there being two distinct fragments, it may be incomplete. Sanson describes the case of a woman, in whom he conceived the fracture to be incomplete; the bone, at its middle, formed a projecting angle, plainly discernible, yet the patient could lift her hand to her head, and by no means could the slightest crepitation be discovered. Delpech mentions a similar case, but explains it by assuming the integrity of the periosteum. In those cases, as well as those numerous ones where the angle is very obtuse, without deformity, crepitation, or loss of power of raising

the arm, it is fair to assume that the fracture is incomplete; I am not, however, aware that any direct post-mortem sanction has yet been given to this opinion.

The clavicle may, as a consequence of violence, be fractured at any part; but as a consequence of indirect violence, the middle is the ordinary seat of the fracture, where, in fact, the bone is thinnest and most curved.

Symptoms.—It is important to determine what is the relation of the coraco-clavicular ligaments to the fracture, because this decides whether it is a fracture of the sternal or the scapular portion of the clavicle. Ribes maintains that if the costo-clavicular ligament is attached to the external portion, the fragments will not be displaced, neither by muscular action nor by the weight of the body; the internal fragment remaining immovable, whilst the external is relaxed by the costo-clavicular ligament. This opinion is certainly much too exclusive, and there is a case in proof of this where a dissection was made by Beclard. If it be fractured at its external extremity, between the acromio-clavicular articulation and the insertion of the coraco-clavicular ligament, the scapula is sustained and there is no displacement; if it happen within that ligament, the external fragment is almost always displaced, whilst the internal, drawn upwards by the cleido-mastoid muscle, downwards by the pectoralis major muscle, and the costo-clavicular ligament, does not change its situation; still a case occurred to Guérétin where the fracture was near the internal border of the coracoid process; there was a good deal of displacement; the external fragment, sustained by the coracoid process, was not displaced; the internal was drawn down by the deltoid and pectoralis major. There is on record an exceptional case, where the internal fragment was drawn up vertically, the cleido-mastoid muscle being spasmodically contracted. Generally the external fragment is depressed by the weight of the arm and the action of the deltoid; it is at the same time drawn forwards and inwards by the pectoralis major, so that it is placed under the internal fragment, which projects above it. The clavicle can then no longer retain the shoulder at its natural distance from the sternum, the arm is depressed, slightly rotated inwards, and the head and the trunk are inclined to the injured side. This attitude is so characteristic that many eminent surgeons believe that they can always, from that fact alone, determine the accident. The patient can no longer bring the hand to the head, because the humerus no longer finds in the clavicle a necessary point of support. Instead of bringing the hand to the head, he brings the

head to the hand. Still, when a patient is unable to execute this movement, you are not therefore to presume that there is fractured clavicle; nor when that ability exists, must you always presume there is no fracture. If the signs to which I have referred exist, you proceed to pass the finger along the bone, when an inequality will be detected; if at that time the arm be moved, pain and crepitation will be produced. If we raise the arm vertically, carrying it at the same time outwards, the fracture will be reduced, and the shoulder will resume its natural form and position. In very rare cases the external fragment has been known to pass above the internal; this was even observed by Hippocrates.

Diagnosis.—The diagnosis of this fracture is usually very easy; when there is no displacement it is more difficult: in the year 1787, at the Hôtel-Dieu, Desault three times saw this variety; if the scapular extremity be the part affected, the fragments having suffered no displacement, it is sometimes extremely difficult to ascertain the exact injury. We examine carefully the painful point, we feel near the acromion a slight depression, and this disappears if the shoulder be raised by pressing up the elbow.

Usually no danger attends fracture of the clavicle, unless there be some serious complication; yet the consequences of undetected simple fracture have been serious; abscess and necrosis have occurred. When it is a consequence of direct injury, there is always a certain quantity of contusion; the bone may be comminuted, and the vessels or nerves may be injured, and paralysis of the arm may follow. (*Med. Chir. Trans.* vol. vii. p. 175.) The bones may pass through the skin, but, except in military surgery, these are very unusual cases.

Treatment.—A fracture of the sternal extremity is usually easily reduced; it is merely necessary to press up the elbow, to raise the shoulder, pressing the arm a little outwards, to reduce it to its proper position; but though reduction is thus easy, maintaining reduction is any thing but easy, as may readily be supposed, when we look at the numberless apparatuses invented for the purpose. Formerly all that was deemed necessary was to keep back the shoulders, as is seen in this apparatus (fig. 1) of Heister's.

But carrying back the shoulders does not remedy the displacement, and the stellated bandage was resorted to. Upon this bandage many changes have been rung by inventors, but most of them are very small improvements on it. Desault made a lever of the humerus, for the purpose of extending the clavicle; this was accomplished by placing thick pads in the axilla, and

Fig. 1.

bringing the arm close to the side; and unquestionably a very important improvement this was. His plan, which, variously modified, is in common use in the present day, was to place a conical wedge in the axilla, its base directed upwards, and secured there by bandage; this being fixed, the arm was brought to the side, the elbow directed forward, so as to carry the shoulder outward and backward. The reduction being thus completed, the next point was to keep the fragments reduced; rollers, after passing around the chest, were brought down from the shoulder and carried round the elbow and arm, so as to fix them securely; then another roller was carried round, and fixed just below the axilla of the healthy side; directed from thence over the injured shoulder, and so continuing until a sufficient protection against displacement was had. To prevent slipping it is well to pass a needle and thread through the turns of the bandage. Still, however well applied, the drawback to this apparatus is, its getting loose; and his experience of that induced Boyer to invent his apparatus, which in principle does not differ from the former.

Mayor's apparatus, like Sir C. Bell's, is certainly more simple, and I think more effective. It consists of a gutter slung around the neck, and brought in front of the chest, but well inclined to the opposite side. In this the arm rests, and by its weight makes tense a strap by which it is supported; and this strap keeps down the clavicle.

Among the modern improvements in the apparatus, is the substitution of a small air cushion, for those formerly used in the axilla, to which two objections attached; they either gave way too much or were too unyielding.

Richter fills up the spaces around the clavicle with compresses, over which the ordinary bandages are placed. I am strongly of opinion that compresses, saturated with starch, or any other substance capable of consolidation, would be a desirable improvement, because, when reduction is completed, it would be exactly adapted to the part, and would be opposed to subsequent displacement: plaster of Paris would answer well for the purpose. Velpeau, after trying most of the apparatuses, has discarded them: he now places the hand of the affected side upon the shoulder of the healthy side, and fixes it there; but certainly, whatever merit it may have, it is a very uncomfortable position for the patient. Between the many apparatuses we have considered, and the catalogue might have been doubled, I have no hesitation in recommending that of Sir C. Bell and Mayor as the best, though no doubt the object may be attained by others; but what extent of deformity may result will depend much upon the skill and attention of the surgeon.

Yet though the variety and apparent completeness of many of the apparatus might naturally lead us to expect that fractured clavicle would be cured without deformity, it happens that such an occurrence is rare; usually there is a slight shortening and projection of the internal fragment, and no means at present known are capable of preventing this. It is true that the deformity is ultimately inconsiderable, and the shortening trifling; but still they are real, though they do not at last interfere with the extent or the precision of the motions of the arm: the consequence of that conviction is, that complicated apparatuses are in the present day to a certain extent exploded, and the means commonly employed are, a pad in the axilla, the arm fixed in the way I have already described, and a shoulder strap to keep down the fragments. The time necessary for consolidation is comparatively short. Some persons have maintained that calcareous matter is very slowly deposited in the callus, and advise that the apparatus should not be removed before the sixtieth day. Certainly general experience is opposed to this view of the case, since the apparatus is most frequently dispensed with by the end of the third week—sometimes sooner. The ancients thought consolidation was accomplished by the twelfth day; and the reason they gave for it was, that the texture of the clavicle was spongy. Whether the energetic action which presides over its development during the first months of intra-uterine life, and which causes it to be one of the first bones ossified, and to be for some time superior in length and bulk to the humerus, still continues to preside over

this bone, I cannot say. If so, is it for this cause that artificial joints are there so excessively rare, that it may admit of question whether a single case has been seen?

THE HUMERUS.

The humerus may be fractured at many points, at its middle portion, or its extremities. If the fracture be above the insertion of the latissimus dorsi, pectoralis major, and teres major, it is termed a fracture of the neck of the humerus; but this is surgical language; for the anatomical neck of the humerus is, as you know, a much more limited space. When it is below the insertion of these muscles, it is termed fracture of its body. A fracture may be transverse or oblique, simple or complicated—may be caused by direct or indirect violence. Muscular contraction alone may be sufficient to fracture this bone. A man, not many years ago, fractured the humerus in an attempt to twist

the wrist of his adversary. A woman fractured her humerus in a violent effort to grasp the wheel of a carriage when she found a foot-path giving way under her. A person has fractured the humerus in throwing a stone. The simple action of drawing on a glove served to fracture the humerus; but, in that case, there was no doubt caries (Fabricius Hildanus); a similar consequence has been produced by missing the object when hitting out (S. Cooper). Probably Fabricius' is not the only one of these cases in which the bones had undergone some organic changes. There is usually considerable displacement in fractures of the humerus, varying with the point injured, and it is very characteristic. If the middle part of the bone be affected below the insertion of the deltoid, and this is the most frequent seat of fracture of the humerus, the displacement is not great, because the brachialis, anticus, and triceps, are attached equally before and behind the two fragments (fig. 2). If it be

Fig. 3.

Fig. 2.

Fig. 4.

above the insertion of the deltoid, the inferior fragment is drawn upwards and outwards to the outside of the superior fragment, which is drawn downwards and inwards by the latissimus dorsi, pectoralis major, and teres major (fig. 3). If the fragment be near the inferior extremity of the bone, the extent of surface prevents any great displacement, though the inferior fragment may be drawn a little upwards and backwards by the action of the biceps. The weight of the arm, however, is opposed to great riding. Still if the arm be very muscular, the inferior fragment is forcibly raised by the biceps, brachialis, anticus, and triceps, and the arm is shortened.

We detect these fractures by pain at the affected part, by the inability to move the arm, by its change of form and direction, by the unnatural mobility of its middle

part, and by the crepitation, which is easily perceived.

Fracture of the humerus is ordinarily not a serious injury. If it be at the inferior extremity, and implicating the joint, it is of course more serious, because incurable ankylosis may be the consequence.

Treatment.—The reduction is usually easy: an assistant sustains the shoulder, whilst extension is made upon the lower fragment, or upon the semiflexed forearm; why you should choose the latter, I have already stated. The fracture being reduced, and the arm having resumed its proper angle and form, the external tuberosity of the humerus being found upon the same line, as the most projecting point of the shoulder, the forearm and hand are rolled to prevent the œdema so commonly

consequent upon those injuries. Many persons continue the roller along the arm with moderate firmness; others, fearing inconvenience from tumefaction, use a many-tailed bandage. Some persons now place four splints of pasteboard or wood; others are satisfied with two, laterally placed; others, and justly, with Amesbury's apparatus, or the starched bandage. Either apparatus may be made tolerably free from inconvenience. If the fracture be simple, it is not absolutely necessary that the patient should be confined to bed at all; in that case the arm is flexed and fixed in front of the chest; from time to time, with intervals of eight or ten days, you examine to ascertain whether there be any displacement, but it is not prudent to remove all support before the fifth or sixth week. If the fracture be complicated with wounds, the patient must keep his bed: in such cases Mayor and Sauter's apparatus will be found useful; it facilitates dressing, and irrigation, if necessary.

INFERIOR EXTREMITY OF HUMERUS.

When the inferior extremity of the humerus is fractured, the diagnosis is not always easy, because the inferior fragment is small, and the swelling about the joint is sometimes great. The triceps may draw the forearm upwards and backwards, carrying with it the inferior fragment, the superior being pushed forward. Goyraud and others have seen the inferior fragment fractured vertically; it has also been observed by Sir A. Cooper. The displacement of the inferior causes a displacement of the superior fragment; the olecranon projects backwards—sometimes considerably; the forearm is slightly flexed. In several cases mentioned by Cooper and Dupuytren, this injury has been mistaken for dislocation. If we bear in mind the following circumstances, we shall not fall into this error:—Fracture is caused by a fall on the elbow; luxation by a fall on the hand, the arm being extended. In luxation, the relation of the olecranon with the condyles of the humerus is changed. In fracture they retain their natural situation. In luxation, the forearm, slightly flexed, is fixed in that position; force is necessary to flex it further, or completely to extend it, and the effort causes much pain. In fracture we can move the forearm; and this movement usually moves the inferior fragment, so as to occasion crepitus. In fracture, reduction is easy, but displacement is reproduced; reduction of luxation requires more force, but, once reduced, there is no tendency to displacement.

Treatment.—In the treatment of this kind of fracture, it has been proposed to place the limb in a state of extension, and to apply

four splints, to include the arm and forearm. Though this position may on the whole answer best as far as apposition is concerned, the pain occasioned is often intolerable, and if anchylosis result, a straight is much less useful than a semiflexed arm; therefore, a partially flexed position is generally preferred. After the limb is properly rolled, elbowed splints, of a proper angle, do best. Some persons employ an anterior splint, which will fit closely into the bend of the arm, and this Sir A. Cooper recommends. After the second week, it is desirable to gently move the arm, for the purpose of lessening the chances of considerable rigidity, or anchylosis.

SEPARATION OF THE CONDYLES.

Separation of the condyles is more frequent in young children than at any other period, and is commonly produced by a fall on the elbow. The symptoms are projection of the epiphysis, fixed pain at the point, increased by pressure, and by flexion or extension of the forearm. Crepitation is sometimes produced by rotating the radius, but that is uncertain. The tumefaction is, however, often so great as to mask the principal symptoms. In the various specimens I have known there was no osseous union.

Treatment.—In treating this injury, the forearm should be flexed at a right angle with the arm: the arm and forearm are rolled; an elbow splint, which in children may be made of pasteboard, must be adapted to the joint; the arm is placed in a sling; and, as early as it can be safely done, the joint must be moved. If there be much contusion or wound, the limb may be placed in a semi-flexed position upon Sauter's apparatus; and if the injury to the soft parts be dissipated before the fracture is united, such an apparatus as I have already described may be applied.

SUPERIOR EXTREMITY OF HUMERUS.

The upper extremity, the surgical, or anatomical neck of the humerus, may be the seat of fracture, but the former is by very much the most frequent. When the surgical neck suffers, the superior fragment yielding to the action of the supra and infra spinatus muscles, is tilted up as in the diagram (fig. 4), whilst the inferior fragment is drawn inwards by the pectoralis major, teres major, and latissimus dorsi, and upwards by all the muscles which proceed from the shoulder to the arm and forearm, but the upward movement is rarely great. If the bone be fractured at the level of the tuberosities, the fragments retained by the tendinous insertions surrounding the fracture are very little displaced. If the head of the humerus be detached, the inferior fragment may be drawn a little up-

wards and outwards by the action of the deltoid, supra and infra spinatus muscles, but even then the displacement is trifling.

Extra capsular fracture of the superior extremity of the humerus is consolidated as in ordinary fractures; but if the head alone be completely detached, it appears to be very doubtful whether osseous union will occur. Stalactiform prolongations may arise from the inferior fragment, and embrace the circumference of the superior fragment, but a false joint is more frequently formed. Indeed it is difficult to conceive life being preserved in the head of the humerus completely detached. Still there are on record eight such cases, in five of which union took place.

It is almost always a direct violence which produces these fractures, and they are usually complicated with considerable contusion. Still a fall on the elbow or the head, the arm being separated from the trunk, will occasionally produce it.

Symptoms.—If the fracture happen at the level of the tuberosities, there will be very little deformity. Pain, and inability to use the limb, will lead us to suspect fracture; but those symptoms are often occasioned by contusion, and we must put the hand upon the shoulder, and endeavour to produce crepitation. If the fracture be in the surgical neck, the deformity will be very apparent; the upper end of the inferior fragment will project in the axilla, the elbow will be removed from the trunk, and a marked depression will exist below the acromion. This condition may be mistaken for luxation downwards; in both there is depression below the acromion, but it is nearer the acromion in luxation. The projection in the axilla is very trifling in fracture as compared with luxation: although the arm is removed from the side in fracture, very little pressure upon the elbow will overcome the resistance; much pain occurs, and more pressure is required, in luxation. The reduction of fracture is easy, of luxation is difficult; the displacement in fracture is soon reproduced after reduction, not so in luxation. Of course, if there be crepitation, all uncertainty is soon dissipated.

Fracture of the superior extremity of the humerus is more serious than that of the body, because of the vicinity of the joint, the violence which has produced it, and the impossibility of exact reduction.

Treatment.—In all these cases reduction is imperfect, because the fragment is too short to allow of the hand exercising any action on it. The limb must be placed in a state of semi-flexion, fixed to the side of the trunk, and supported by a sling. Where the surgical neck has suffered, the only effectual means of applying any pressure upon the part is to moisten the bandages which are passed on the shoulder in white

of egg or starch, so as to fix them to the point. Sir A. Cooper, after rolling the arm from the elbow to the shoulder, places two splints on the internal and external surface, places a cushion between the chest and the arm, and places the arm in the sling. Probably no apparatus will exactly restore the conformation of the part, because none acts on the superior fragment; but the slight deformity which results is of no consequence. The apparatus should remain applied for six or seven weeks.

THE FOREARM.

The superficial situation of the two bones forming the forearm, their size, their mode of articulation with the humerus, which does not allow of lateral movement, are sufficient reasons to account for the frequency of their fracture. The radius is more frequently fractured than the ulna, because it, almost alone, sustains the hand, and the shocks produced by falls upon the hand are received by it; there is, however, a case mentioned by Berard, where, by a fall upon the hand, both bones were fractured. Though fracture of both bones may occur at any point, the middle and the inferior suffer much oftener than the superior extremity. Usually both bones are fractured at the same level, but this is not constant. Such fractures are almost always caused by direct injury, and therefore it is that comminution and contusion are not unfrequent. There is almost always displacement when there is simultaneous fracture of these bones; this I admit, though I am not disposed to go so far as many surgeons in support of the opinion, that much displacement may result from the action of the pronators. The superior fragment of the ulna, firmly articulated with the humerus, is the only one not displaced. Displacement as to length is difficult, because the interosseous ligament is opposed to it.

Fracture in these bones is detected by the change in the form and direction of the limb, by the mobility of the forearm at the fractured point, by crepitation, by the difficulty of bringing the limb prone or supine, and by the severe pain which is felt when such motion is attempted. When the fracture is seated near the wrist, formerly, and even at present, it is very often mistaken for luxation of the wrist.

Simple fracture of the forearm is generally not a serious injury; still, if not carefully attended to, the radius and ulna may unite together, though it rarely happens, and pronation and supination be lost. Even when complicated, fracture of the forearm is much less serious than a similar fracture of the leg.

Reduction of this fracture is usually easily accomplished. The patient sits on a chair; the forearm is flexed, and half prone; an assistant takes the hand, and

makes extension, another makes counter-extension above the elbow. The surgeon stands on the outside of the limb, places the fingers of each hand upon the anterior, and thumbs upon the posterior surface of the forearm, as near as may be at the level of the interosseous space. The reduction made, if necessary, compresses, imbibed with some evaporating or cooling lotion, are applied; if not, some persons prefer rolling the arm, from the fingers up to the elbow, with starch or common bandage: in the latter case, a couple of splints are applied on the dorsal and palmar surface of the arm, and fixed there by rollers. The arm is then semiflexed, placed between pronation and supination, and supported by a sling, across the chest: some persons place the palm against the chest, but the diagrams show that the proper attitude is

Figs. 5. and 6.

that in which the palm is directed upwards, so that, in the language of an old preceptor of mine, you can spit in it.

It is wise to examine the arm every ten days, to ascertain that pronation and supination are not deranged; from the fourth to the sixth week, consolidation is complete. When the fracture is seated near either extremity of the forearm, towards the end of the treatment they must be gently moved, to ascertain that false ankylosis is not taking place. Some persons place at the dorsal and palmar surface, between the bones, a cord-like compress from the elbow to the wrist, to prevent union taking place between the bones: there is not, however, much fear of this; for in museums, although we may see many cases of very deformed union, we very rarely see a specimen in which union has taken place between the bones.

THE RADIUS.

Fracture of the radius is much more frequent than that of both bones. This is caused principally by the connections of this bone. They may be transverse or

oblique, may occur at the middle or towards the extremities of the bone; may be a consequence of a blow received on the bone itself, or a fall upon the palm of the hand. In the latter case, the bone is pressed between the hand and the humerus, which supports the weight of the trunk, and, it is said, often fractured in the middle third. My experience certainly does not favour this conclusion.

In length no displacement occurs; superiorly and inferiorly the fragments are retained by the articular apparatus, and also by the interosseous ligament. It is said that they are drawn towards the ulna by the pronator and other muscles, but I have never been able to satisfy myself that much influence is exercised in this way.

Diagnosis.—When, after a fall on the palm or a blow on the radial border of the forearm, severe pain and inability to pronate or supinate are experienced, a fracture of the radius may be suspected: to confirm or reject the suspicion, the fingers are passed carefully along the radial border of the forearm. If there be fracture, we feel at the painful point a depression, an absence of resistance, or even an inequality of the fragments; pronation and supination are painful, and may occasion crepitation. If the fracture be near the superior extremity of the bone, it is not so easily detected, because of the thickness of the soft parts which surround it. In such a case, it has been advised to fix the superior extremity between the finger and thumb, whilst we impress upon the inferior fragment pronation and supination; but in a fat arm this is not easily done. Difficulties have been experienced in detecting fracture of the inferior extremity of this bone. There is little displacement towards the ulna, because the bones are naturally almost in contact in this region, and it has often been mistaken for luxation of the wrist. Upon this point, Cline, Cooper, and Dupuytren, have thrown much light; the latter surgeon doubts the possibility of luxation of the wrist; but here, as we shall see, he was wrong. If it be true that such an error may not be seriously injurious to the patient, it may certainly damage the reputation of the surgeon. This fracture may or may not implicate the radio-carpal articulation. It is always more serious than that of the middle third of the bone, because of the rigidity which it leaves after it at the joint, and which is very slowly dissipated, especially in old men. Crepitation and the slight displacement shewn below (fig. 7), are our only guides. If the patient be very young, the mobility of the inferior fragment may be very sensible; but then crepitation may be wanting, for it may be only the separation of the epiphyses.

Fig. 7.

Treatment.—The treatment of fracture of the radius is similar to that of the forearm; only that direct extension is not necessary, but simply inclination of the hand towards the ulnar border of the forearm, so as to act principally on the radius. If we drag equally on the two bones, a portion of the force will be entirely lost on the ulna. Dupuytren's splint, of which the following is a modification, accomplishes that ob-

Fig. 8.

ject, by removing the inferior fragment from the ulna, and preserving the interosseous space, but it offers no obstacle to the displacement of the superior fragment.

ON THE INFLUENCE OF LIQUIDS

ON THE BODY IN HEALTH AND DISEASE.

By MELBOURNE B. GALLWEY,
Assist.-Surgeon Royal Artillery.

[Concluded from page 356.]

THE safety-valve against engorgement of the blood-vessels, where liquids have been consumed in inordinate quantities, is resident in the skin, in the lungs, and in the kidneys. "All soluble matters," according to Woeller, "which do not suffer decomposition in the system, but more especially the superfluous matters, are got rid of by means of the kidneys." "The excretion," says Müller, "of superfluous water from the blood by the kidneys appears to take place with extreme rapidity, it nearly keeping pace with the absorption of watery fluids from other parts of the body into the blood." I knew myself a remarkable instance of a man, in whom the idiosyncrasy existed, being able to evacuate urine at the moment of drinking, and of continuing to do so as long as he kept up the supply of liquid by the mouth; and this, though the bladder should have

been empty but the moment before. We require, indeed, no accumulation of facts to convince us that, in a state of health, the kidneys alone might of themselves, perhaps, be capable of excreting all the fluid which we introduce into the circulation, and this very probably is the principal office of these organs. I say the principal, because we must bear in mind their important function of separating urea, and other salts from the blood. But this activity in the office of the kidneys no longer obtains in disease. In febrile and inflammatory affections we notice invariably a diminution of this secretion, whilst there is no equivalent increase of perspiration or of pulmonary vapour. In cholera we see it altogether suppressed, a disease in which the urgency of thirst is only allayed by excessive potations of water; and, did not the latter find a speedy and extraordinary escape through the exhalants of the intestines and of the skin, (the capillaries of which are here unusually paralyzed), we might surely anticipate general dropsy, if not coma, from engorgement of the cerebral vessels, or apoplexy from a rupture of them.

It is a matter of question, I think, how far the abstraction of liquids from the patient might not be of service, in that morbid condition of the system where the secretion of urine is entirely suppressed during a state of otherwise apparent health*, a disease which Dr. Willis defines by the term *anuria* *apyretica*. Whether dependent on an alteration of structure, or functional only in character, the disease is one of the most formidable we can encounter; and about the treatment of which we must busy ourselves so early, that, to the attendants around, the patient would seem to have nothing the matter with him, if we desire to stay its fatal progress. In such cases, it is usual to pour diluents into the blood, with the hope of determining them to the kidneys; but such means are seldom sufficient, nor, indeed, is any other treatment that we know of. Coma sets in rapidly; and the patient dies apoplectic. Supposing, however, the suppression of urine to supervene on an injury to the spiuë,

* I remember an excellent paper on this disease, in one of the numbers of the *MEDICAL GAZETTE*, of some three or four months ago. The author (whose name I forget) detailed some interesting examples of the affection, all of which I think had a fatal result.

or on well-marked disease of the kidneys, where the system takes the alarm, and other secretions besides itself are suspended more or less; supposing, too, that the kidneys are obstinately indisposed to be influenced by diluents, I hold that the farther administration of them can do no nothing less than hasten the comatose affection of the head; and that the pressure on the brain, which is often believed to result from the regurgitation of urine thereon, and into the cavities of the organ, is fully as likely to be aggravated if not mainly produced by the engorgement which this practice entails on the blood-vessels.

I would particularly recommend an abstinence from drinks to be observed in the treatment of scarlatina, more especially if the patient happen to be of a sanguine temperament, or a plethoric habit of body: and this precaution I insist on, because of the dropsical sequela which frequently results on the disease, a feature in its history which occasionally imparts to it a tragical complexion, even when the primary symptoms may have been unusually mild. This interdiction of liquids, in scarlatina, I hold to be called for, if there is anything of truth in what I have offered concerning their misapplication in febrile and inflammatory diseases: for, on the same principle, and on the same account, I venture to call in question the propriety of their exhibition here, as I did when reviewing their influence in the latter conditions. Of the pathology of this particular form of dropsy we know very little; but whether it proceed from an inflammatory tendency lurking in the system, or from an absence of tone in the vessels, the employment of liquids must be equally injurious. So convinced am I of the reasonableness of such an objection, that, during the fall of the last and the spring of the present year, when this garrison had been infested with scarlatina in common with the other exanthemata, I made the experiment of withholding liquids in the treatment of such particular cases as I was able to exercise a rigid interference in, with a view to determining the extent of their influence on the subsequent dropsy. That I might not be biassed unfairly in my observations by the view I had preconceived of their influence, I made a selection of cases, the notes of which I

have now before me, and treated as many as twenty on the dry plan, whilst, to a similar number, I urged, as a part of the treatment, that water might be freely and frequently allowed. That the result which ensued was the consequence of accident may possibly have been the case. It was this. Out of the number treated on the former plan, one only was attacked with anasarca on the close of the disease: but of those to whom water was liberally administered, six were subsequently affected with anasarca of the face and extremities; one died of well-marked hydrocephalus; and another of hydrothorax combined with ascites. How far the effusion into these vital cavities, in the two latter cases, was connected with the previous scarlatina, I pretend not to determine. It is enough that I register the facts. And how far the total withdrawal of liquids, in the former cases, may have had to do with the subsequent immunity from dropsy, is a question which we can only speculate upon, although the presumptive evidence, I think, is strongly in favour of the tenableness of my position.

If the preceding observations should hold good in relation to the sequela of scarlatina which I have spoken of, they must not less apply to dropsical affections in general. The hydropic subject drinks, and that too often to excess, (for, wherever there is a large demand on the watery portion of the blood, whether through the intestines, the skin, or other texture, there is thirst in attendance proportionally great) to supply the waste occasioned by the escape of the aqueous part of the blood into the cavities or the cellular tissue of his body. "But," says Cullen, "by withholding the use of fluids in dropsy, you will diminish the quantity of fluids secreted, and allow the secretories of the kidneys to fall into a state of inactivity and collapse." Paris quotes and considers this maxim as a sufficient answer to those who defend the practice of enjoining an abstinence from all fluids in dropsy. But, on this point of contention, I venture to be at issue with Cullen, and think his position particularly untenable, under circumstances where the secreting organs, as is sometimes the case, are losing ground in the race between the activity of the exhalants and themselves. I think, if we reason on the matter, that everything

is in favour of the assumption that excessive quantities of liquid are injurious in a case where the mouths of the exhalants (if I may so speak) are constantly patulous, and pouring their contents into the cavities of the body as rapidly as they can be supplied to the circulation, and where, again, the absorbent energy of the system is enfeebled or inert. The effect will probably be slow and imperceptible at first; but not less certain, I think, if the indulgence in liquids be persevered in,—

"Gutta cavat lapidem non vi sed sæpe cadendo."

Besides, we are accumulating the amount of evil in another way, inasmuch as the indulgence in drinks, to the extent to which they are coveted, must impoverish the quality of the blood, and disable it the more from making head against the disease. Still much must be hypothetical here; but, in the absence of knowledge more substantial, we should choose the hypothesis most consistent with reason, and in accordance with our senses. Those who are familiar with the beautiful lectures of Dr. C. B. Williams, published some time ago in the *MEDICAL GAZETTE*, on the diseases of the thorax, will remember that he urges the withdrawal of liquids, in the treatment of catarrh, as a means the most powerfully calculated to knock that affection on the head at the outset of its career.

Enough has been said already on the frequency with which the secretions of the skin and of the kidneys are diminished in disease. Supposing this state of inactivity to continue for any time, and the influence of medicine insufficient in restoring them, it follows assuredly that liquids, if persisted in further, can only escape through the exhalants of the intestines, or by evaporation from the pulmonary mucous membrane. On the first of these outlets, I need say very little, since the torpor or spasm, if you will, of the intestinal capillaries in general, keeps pace with the like condition of the vessels of the kidneys, and of the surface of the body.

Concerning the latter system of vessels, viz., the exhalants of the lungs, we have no decided evidence, perhaps, of the suspension of their function in disease; although from analogy we are certainly warranted in supposing them to harmonize in their action with the secretory vessels of other organs.

"There can be no doubt," says Paris, "that, in certain states of disease, the exhalants of the lungs, like those of the skin, are affected by a spasmodic constriction, in consequence of which the usual quantity of fluid for the lubrication of these parts is not effused; whence a train of morbid phenomena arises." To what extent the vapour from the lungs is capable of being increased, under certain emergencies of the system, we are as little able to determine; but it does not appear that the amount of this exhalation is ever very large during health, experiment having failed hitherto in estimating this with any precision. Cruikshank, in his experiment of breathing for the space of an hour into a bottle, and of collecting the vapour which had condensed in it at the end of that period, observes, "If I lost a hundred and twenty-four grains of vapour, by respiration, in an hour, at the same rate I should have lost six ounces, one drachm, and thirty-six grains in twenty-four hours." Sanctorius, from experiment, estimates the amount at a much greater average; whilst Paris assures us more recently still, "that twenty ounces of water are given off by the lungs during the twenty-four hours." It is not very easy to account for the discrepancy in the results of these several physiologists; the less so, as Cruikshank performed his experiments with every attention to the most minute consideration which could influence in any degree the correctness of his deductions, and this, too, with uncommon labour and undiscouraged zeal.

Thus have I spoken at length on the probable influence of liquids in diseases in the which they are freely administered to allay the accompanying thirst; and I have done this more particularly with a view to call in question the propriety of that practice which sanctions at present their exhibition under the circumstances in which I have noticed them.

It now only remains for me to offer a few observations on the operation of liquids, which are destitute of nutritive properties, on the animal system in health.

Wilson Philip remarks, in his *Treatise on Digestion*, that "In respect to fluids, water is evidently intended for the proper dilution of our food." But this is not the only, nor does it appear to be the principal purpose for which we are induced to drink, which seems generally to

be, to supply the waste of moisture occasioned by the various secreting surfaces, and particularly by the skin, which is the most extensive; hence everything which promotes perspiration increases thirst. For a similar reason, diarrhœa, and the operation of a cathartic, have the same effect. I feel by no means certain, that matter is wholly devoid of some inherent nutritive property, resident either in itself or the elements of which it is composed; else, how shall we account for the obesity which follows occasionally on an inordinate indulgence in tea, and in similar liquids?

There is an interesting passage in Paris's *Pharmacologia*, on the very question. "Water," says he, "under certain circumstances of the body, appears to suffer decomposition, and to have its elements appropriated to new combination. Count Rumford has endeavoured to prove, that the surprisingly small quantity of food which is sufficient for nourishment, when converted into rich and palatable soups, is owing to the culinary process having prepared the water for chemical decomposition,* and that this is ultimately effected during the act of digestion." "It cannot be denied," continues the same, "that exorbitant potations of water have a tendency to produce fat; but this may depend upon the vascular distension which is thus occasioned." "Gin-drinkers, before they become materially injured by the habit, grow extremely corpulent, as may often be witnessed in unfortunate Cyprians of the lower orders. Can the hydrogen of the spirit contribute to this effect?"

I have said that an excessive indulgence in tea, and in *slops* of a similar nature, has a tendency to engender obesity. I should rather say, perhaps, that it *seems* to produce such an effect, for I know of no facts which can positively establish the relation of cause and effect between them, beyond what my own observation has taught me to conclude, and what has been insisted on by others who have paid particular attention to the influence of liquids on the system. A celebrated physician of the present day, well known for the abstinence from liquids which he enjoins in disease, was asked in my hearing, "how a tendency to corpulence might be overcome," when

he replied to his patient, by inquiring into the quantity of tea which he consumed in a day? "Two and often three breakfast-cups full I always drink in the morning, and at night, said the applicant." "Reduce your allowance to one at most," replied the other, "and you will cease to grow fat." I mention this anecdote, unimportant as it may seem, from the fact of the physician being one who deduces his knowledge from the book of nature itself, and than whom few have had more extensive opportunities of studying it. And "he that giveth his mind to observe, will meet with many things, even in vulgar matters, worthy of observation." I admit, however, that potations of watery drinks, howsoever freely indulged in, will not invariably produce this effect on each and all of its votaries; because there are individuals in whom absorption so equally keeps pace with the deposition of fat, that, do what they will, and commit no matter what excesses, such persons will often not acquire an addition of six ounces to their weight, no—not perhaps in as many years; whilst others again have a natural predisposition to obesity, which, though they may lower the scale of their diet to the lowest point consistent with safety (and, many there are of the opposite sex, whom the *cito pede* march of *embonpoint* reduces, from motives of vanity, to such an alternative), still gains ground upon the inactivity of the absorbents.

We are much in the dark, in good truth, concerning this matter, and know very little of the laws which regulate the deposition and absorption of fat. Nevertheless, I maintain, that its deposit is a consequence frequently of fluids, which would seem to contain nothing manifestly nutritive in them; but whether this arises alone from a distension of the blood vessels, or from any other *physical operation* which we know not of, must in the present state of our knowledge continue undetermined.—But, it will be said, in disproof of the *fattening tendency of water*, that the miserable objects amongst the poor, who subsist so extensively on tea, and who really are in the habit of making this article their dinner or principal meal in the day, are notoriously wan and emaciated, present the aspect of inanition, and seem prematurely falling into the condition of the "lean and slippered pantaloons." And so they are—the ob-

* "Fish, especially those of the cetaceous tribe, constantly decompose water, and live upon its hydrogen."—Paris's note on the above.

jection is unanswerable, in so far as the simple fact is concerned. But, in their case, we notice this striking peculiarity, this palpable difference between theirs and the classes above them in society, who indulge in the article in question, not through necessity, but rather as a luxury; viz., that, whilst the former have *little else besides* their tea to live on (which supports, because it refreshes, or excites them) the latter, in addition, are pampered and supported with *that little else besides*; so that in their case it is an addendum to their more substantial diet, and is only partaken of when the vascular system is already perhaps overloaded with its contents. Dr. Uwins, in his Treatise on Indigestion, has these pertinent and excellent remarks on the present subject:—"Amongst the poor of the metropolis, we are sorry to see the custom so generally prevalent, of taking tea at almost all times of the day; since the temporary stimulus that it gives is followed by that sort of relaxation of nerve and depression of spirit which induces the consumer to resort to a still more reprehensible and baneful custom, viz., that of taking raw and ardent spirits; a practice respecting the mischief of which there can be no room to doubt."

Woolwich, May 6th, 1840.

ON A NEW SPECIES
OF
BILIARY CALCULUS.

To the Editor of the Medical Gazette.

SIR,

WHILST engaged in examining the extensive collection of calculi, in the museum of the Royal College of Surgeons, which had been entrusted to me for that purpose by the board of Curators, I remarked, among those in the Hunterian collection, one which, from its extreme lightness and peculiar appearance, I was led to suspect had been incorrectly described in the manuscript catalogue as consisting of the "mixed phosphates."

This calculus was externally of a dirty-white colour, and had the greasy feel of cholesterine calculi. It floated on water; and, when applied to the tongue, left an impression of bitterness. It was of an oval figure, slightly flattened, one inch and a half in length, rather better than

an inch in thickness, and about an inch and a quarter in breadth; but, being broken in this direction, its exact measurement could not be ascertained. It readily yielded to the knife, and the cut surface had a polished appearance. Its structure was lamellar; being composed of white and reddish-yellow layers, arranged concentrically, and alternating with each other: the layers were easily separable. At its centre there was a small vacuity.

When heated before the blow-pipe it readily fused, then caught fire, burning with a clear flame, and giving out the smell of animal matter, but nothing of an urinous character. It left a carbonaceous residue, which, by raising the heat, was converted into a white ash. This ash was alkaline, dissolved in water and dilute acetic acid, and the solutions gave a white precipitate with oxalate of ammonia: it was therefore lime.

When digested in boiling water, the water became slightly brown, but no apparent solution took place; the water, on evaporation, left a transparent yellowish brown residue, which had a bitter taste, and resembled inspissated bile.

Boiling alcohol extracted from it only a minute quantity of white fatty matter, which was deposited on cooling.

A solution of caustic potass removed the whole of the yellow colouring matter, but the rest of the calculus was unacted on. The potass solution was dirty green; and, when neutralised with muriatic acid, deposited a scanty precipitate of the same tint.

When digested in nitric acid, effervescence took place with the escape of a little nitrous acid; it then melted into a transparent oil, which, on cooling, concreted into a white fatty matter. This substance, when washed with distilled water, melted at a temperature much below that of boiling water.

When, instead of nitric acid, muriatic or acetic acid was employed, the portion of calculus did not melt until it had been removed from the acid; it then presented a similar appearance to that obtained by the action of nitric acid: consequently, this white fatty matter was not formed by the action of the nitric acid.

In all these cases the acids retained lime in solution.

The fatty matter, separated by the action of acids, was partially soluble in boiling alcohol; and the solution, on cooling, deposited shining crystalline

scales. With caustic potass, it formed a ropy, almost gelatinous solution, and was precipitated in white flakes on the addition of an acid.

A small piece being placed on the bulb of a thermometer previously heated, began to solidify when the temperature had sunk to about 135° Fahrenheit.

From these experiments I concluded, that this calculus consisted of margarate or stearate of lime, mixed probably with the oleate of the same base, and some of the other constituents of the bile. That the lime was in combination with the fatty acid was indicated by the insolubility of the calculus either in alcohol or caustic alkaline solutions, until it had been previously digested in some acid.

The minute quantities on which I had hitherto operated prevented me from determining whether only one or more of the fatty acids were present. The following analysis was therefore made:—

ANALYSIS.

12.80 grains of the calculus, previously dried *in vacuo* over sulphuric acid, were boiled in distilled water. A peculiar odour was given off, and the water acquired a yellowish-brown colour. Being evaporated to dryness, it left a transparent resinous-looking residue, which weighed 0.84.

This residue, when digested in alcohol, left 0.24, in the form of dirty, yellow flakes, which, in distilled water, swelled up and ultimately dissolved, forming a solution which, in its chemical character, exactly resembled that of the mucus of the gall-bladder.

The alcoholic solution being evaporated to dryness, the residue was re-dissolved in water; the solution was intensely bitter.

With muriatic acid it gave a copious viscid precipitate; acetate of lead produced likewise a viscid precipitate; and the supernatant liquor, when clear, was again troubled by a solution of sub-acetate of lead.

The 0.84 consisted, therefore, of mucus of the gall-bladder..... 9.24

Inspissated bile..... 0.60

After water had extracted from the calculus all that it was capable of dissolving, it was treated with successive portions of boiling alcohol.

The first alcoholic solution, on cooling, deposited a white matter, which did not readily re-dissolve in hot alcohol, or in æther, but was acted upon by acetic

acid. It appeared to be part of the calculus that had been simply dissolved; the quantity, however, was too minute to be estimated. The alcoholic solutions were filtered, and, being mixed together, the whole was gently evaporated. As the liquid became concentrated it deposited some white fatty matter, and acquired a yellow tinge; a residuum was ultimately left, which had the appearance of a mixture of a fluid and concrete oleaginous substance. On the application of heat it became a yellow oil, which, on cooling, only partially solidified. It weighed 0.47.

It strongly reddened litmus paper; dissolved readily in a cold solution of caustic potass; and was precipitated in soft flakes on the addition of an acid.

This substance consisted, therefore, of oleic acid mixed with margaric and stearic acid.

Strong acetic acid, diluted with twice its bulk of water, was now poured over the calculus, and the action of the acid aided by a gentle heat. The insoluble residue was collected on double filters, washed and dried.

The acetic solution, with its washings, was reduced to a small bulk, and a solution of ammonia added. After the lapse of several hours no precipitate appearing, the excess of ammonia was nearly neutralised by a solution of oxalic acid; a white precipitate fell, which, when washed, dried, and heated to a dull redness in a platina crucible, left 2.09 carbonate of lime = 1.17 lime.

The remaining liquid being evaporated to dryness, and the ammoniacal salts expelled, a residuum was left, which weighed 0.10. Water dissolved a portion of this. The solution was alkaline; and, when evaporated, minute crystals were formed, which slightly effervesced in acetic acid. Their solution not precipitating chloride of platina, leaves little doubt of their being carbonate of soda; the small portion which remained undissolved proved to be carbonate of lime.

The matter left upon the filter after the action of the acetic acid was again digested in boiling alcohol. A considerable portion dissolved, and the remainder had acquired a much deeper colour. It was collected on the same filters, which were repeatedly washed with boiling spirit. When dried and weighed against the outer filter, it amounted to 0.86.

This substance possessed a brownish-yellow colour; it dissolved in solutions

of caustic and carbonate of potass, forming solutions having nearly the same colour.

Muriatic acid rendered it green; and, when added to its alkaline solution, threw down green flocks. With nitric acid it formed a red solution.

This substance was, therefore, identical with the colouring matter of the bile, and which forms the principal constituent of the biliary calculi of oxen.

The alcoholic solutions were concentrated by careful distillation in a small retort. The liquid remaining in the retort, when cold, formed a soft crystalline mass, composed of brilliant plates, and having a pearly lustre, very much resembling margaric acid.

This substance, when fused, and kept for some time in *vacuo* over sulphuric acid, weighed 8.88 grs.

It melted at 136° Fahrenheit, and on cooling became a crystalline solid, reddened litmus paper, and was easily soluble in a cold solution of caustic potass. The solution, when concentrated, was ropy and gelatinous; when dilute, it formed a slightly milky mixture, with minute glistening particles floating in it. On the addition of an acid, the substance was thrown down in the form of white flakes, which possessed the same properties as before solution.

When boiled with the alkaline carbonates, it was dissolved, with the escape of carbonic acid.

By re-dissolving it in hot alcohol, crystalline plates were deposited on cooling, which after washing with cold spirit, fused at about 140°. The low fusing point of this substance evidently indicates the presence of oleic acid. In order to ascertain whether the crystals fusible at 140° were pure margaric acid, or stearic acid rendered more fusible by an admixture of oleic acid, they were again dissolved in warm spirit, and the crystals, as soon as formed, dried by compression between folds of blotting paper. By repeating this process two or three times, the fusing point was raised to nearly 160°. This must, therefore, be regarded as pure stearic acid; and as I find that both stearic and margaric acids require to be several times re-crystallised from their alcoholic solutions, to free them from even small quantities of oleic acid, and as no decided indication of the presence of margaric acid could be detected in the mother liquors, I am induced to believe that, by the above

treatment, oleic acid only had been separated, and that, consequently, margaric acid did not enter into the composition of the calculus. It would, however, be impossible to speak decidedly on this point. The result of the analysis is as follows:—

Stearic acid, mixed with a small proportion of oleic acid.....	9.35
Lime.....	1.17
Soda, with a trace of lime.....	0.05
Yellow colouring-matter of the bile	0.86
Inspissated bile	0.60
Mucus of the gall-bladder	0.24
	<hr/>
	12.27
Loss.....	53
	<hr/>
	12.80

The greater part of the loss in this analysis should be added to the stearic acid, as owing to the sudden extrication of vapour while under the receiver of the air-pump, a small part of the acid was lost; but I have preferred giving the weights actually obtained, to making any allowance for known sources of error.

The composition of this calculus clearly points out its biliary origin; but whether from man or the brute must remain doubtful, as there is no history to guide us.

Stearic, margaric, and oleic acids, exist in the bile of oxen in combination with soda; and according to Lecanu and Casaseca,* stearic and oleic acid in that of man; the latter I have frequently detected, but I cannot find that these acids have ever been noticed as entering into the composition of biliary concretions; much less forming the prominent constituent. I was unable to detect the slightest trace of these acids in five specimens, selected from about 200.

From cholesterine calculi, it is readily distinguished by the absence of any crystalline structure when broken, which, unless the quantity of colouring matter be very large, is always more or less apparent in that variety; also by its insolubility in alcohol or æther, and by readily dissolving in these menstrua and in a cold solution of caustic potass, after it has been acted upon by an acid.

Before I conclude, I am anxious to rectify an error which I inadvertently

* Gmelin, *Handbuch der Chemie*.—*Journal de Pharmacie*, 12.

committed in my paper on the calculi in the Museum of St. Bartholomew's Hospital; I there stated, that urate of ammonia had always been confounded with the uric acid variety, in the tables that had been published on the relative frequency of the different species of calculus. This was not, however, the case in a paper by Dr. Yelloly, in the *Philosophical Transactions* for 1839-30, containing the analysis of the Norwich collection; and I regret that I have not had an opportunity of making this acknowledgment sooner.

THOS. TAYLOR, M.R.C.S.

New Bridge Street,
May 9th, 1840.

A notice of this calculus was sent to the Board of Curators, in March 1839, but a variety of circumstances have delayed its publication.

INDIGENOUS MEDICINES.

To the Editor of the Medical Gazette.

SIR,

AT a time when the unusual warmth of the season has once more invited the botanist to resume his researches into the treasures of the vegetable kingdom, allow me to impress upon your readers the expediency of encouraging a better knowledge of the sanative virtues of the vegetable productions of our own soil, which have been for so many years overlooked, and where late experience has shewn that there are many valuable though unknown remedies, often equal, and, in some instances, superior to the roots and seeds imported from abroad. An overweening reliance on the efficacy of native herbs was one of the foibles of our ancestors. Ours is in the opposite extreme. The intercourse we hold with every part of the globe has introduced so great an abundance of exotic medicine, as to draw off our attention from the productions of our own country. The accession of remedies, too, from the mineral kingdom, has still further increased this neglect. But without implicitly subscribing to the opinion entertained by many able physicians, that in every country there are to be found indigenous remedies suited to the diseases of that country, it is beyond all controversy, that the fashion of the age, and the prejudice in favour of every

thing that is foreign, has excluded cheaper, and, in some instances, more efficient means, to be had nearer our own doors. I shall not be understood, of course, as in the slightest degree disparaging the use of exotic remedies, where the same benefit cannot be derived from native productions; but I do not see the wisdom of ransacking every corner of the habitable globe, at so much labour and expense, for what may be, in so many instances, supplied more efficiently in our own fields.

In testimony of the truth of this, we have only to look to the valuable catalogue of remedies, some of which have enriched our *Pharmacopœia*, the productions of our own soil—such, for instance, as the hyoscyamus, conium, belladonna, stramonium, digitalis, ilicine, salicine, bronza, ergot, and some others, and, from long experience in the use of indigenous herbs, I feel convinced that it is owing to nothing but our own neglect, that the catalogue of native remedies is not much greater.

But a few years ago the medical world were unacquainted with the remarkable properties of digitalis, and its power over the circulation. Its use even in spasmodic and hydropic affections was not known. The substance of what we are told by the older writers is, "that it was used for rheumatism and other stubborn complaints; that it works violently upwards and downwards, and cures also quartan agues, &c., &c." Medical men were afraid to use the hemlock, before Dr. Stork introduced it into practice, and proved satisfactorily that it might be taken in small doses with great safety, and that, without at all disordering the constitution, or even producing any sensible operation, it sometimes proves a powerful remedy in many obstinate disorders; and yet such is the state of botanical knowledge, that other herbs have occasionally been mistaken for it. The stramonium, though not perhaps indigenous, is of common growth; yet, as a remedy, was not used before Dr. Storck employed it in mania and melancholy; and since his time it has been used in a variety of ways, and sometimes with benefit. Some of the properties of the colchicum have been long known; but its use was partial, as it was regarded principally as a diuretic.

The same observations will apply to some other indigenous herbs, and if, as I trust, the attention of the medical

world be once more drawn to this neglected department, a rich harvest of discoveries will ensue, and our present ignorance of the virtues of our own indigenous herbs will be regarded as a matter of surprise to future ages.

The flowers, the leaves, and every part of the taxus (the yew), indigenous in this country, are known to be of a poisonous nature, but on the authority of an Italian physician it is affirmed, that yew leaves, when administered in small doses to man, have a power similar to *that of digitalis on the action of the heart and arteries*, in a similar manner reducing the circulation, and if persisted in too long, or given in too large doses, as certainly fatal. It is, however, further said to have one decided advantage over digitalis, by its effects not accumulating in the system; so that it is a much more manageable and more efficient remedy.* I have been informed that a decoction of yew leaves, applied during the violence of a neuralgic paroxysm, has imparted a temporary cessation of pain; but I am not aware that in this country any attempt has been made to administer any form or preparation of it internally, or to use it as an external application.

Take another equally dangerously poisonous plant, the cause of many fatal accidents, the *ænanthe crocata*, and which is considered by Dr. Christison as the most energetic of narcotico-acid apiaciæ. Even this has been used in lepra and ichthyosis; and Dr. Hope found an infusion of the leaves useful in promoting the menstrual discharge.

There are six species of the papaver, described in Smith's "*Flora Britannica*," and many of them to be found in every part of the country; yet, what comparatively little use is made of them. How many valuable herbs, possessing diuretic properties, of which no notice is taken? Among these may be mentioned the *polygonum hydropiper*, *paritaria*, *spartium*, *pyrola rotundifolia*, *pyrola minor*, *daucus sylvestris*, and the *asperula odorata*. The last of these, to which authors ascribe such little virtue, appears to me to possess very remarkable diuretic properties. In some cases of abdominal dropsy its use has been followed by a considerable increase of urine, and diminution of the size of the abdomen. There are many other indigenous

herbs, too, which are well known to exercise an influence over the urinary organs. Some, like the *bryonia*, produce vomiting and purging; but whether this active property can be controlled by art, so as to be made available for the purpose of medicine, experience has not yet decided. The *scrophulariæ* possess also purgative and emetic properties. The *linum catharticum*, however, is very frequently employed by medical men; sometimes alone, as a gentle aperient; at other times, along with senna or some other purgative.

I may also mention the *menyanthes trifoliatum*, as a very useful herb; also, the *fumaria*, a common weed in dry waste ground, the herbage of which is bitter, slightly diaphoretic, and aperient: the juice was formerly administered in cutaneous disorders and obstructions of the urine.

The *euphrasia*, though it has lost its reputation in diseases of the eye, yet is still said to be useful in catarrhal inflammations of the eye: it is even said to be beneficial in catarrhal affections in general. The *solidago* and the *achilla* are extensively used in some parts of the country. But the names of English herbs I have already enumerated, are sufficient to show how desirable it is, to investigate this subject with more attention than has hitherto been given to it. The power which chemistry has given us, of concentrating the active principle of many herbs in a small compass, has already been applied with success to some indigenous herbs: a specimen of pyroline, from the *pyrola rotundifolia*, was sent to me some time ago, which was administered in the form of pills, which acted as a diuretic, and at the same time improved the appetite.

But great care will be required to avoid the errors of the older writers, who do not always agree in the properties they ascribe to herbs; some overrate the virtues which they have discovered, others attribute a curious medley of heterogeneous properties to the same herb, so that there is scarcely a disease, to which one or other of these properties might not be expected to give relief. The usual consequence of excessive panegyric has followed. Finding some at least of these ascriptions erroneous, we come at last to discredit the whole. Probably, one cause of such frequent errors arose from the mode of making preparations from the plant, as well as the time

* Burnet.

and manner of gathering them. The virtues of different plants reside principally, though not entirely, in certain parts of them; and we find that some prefer the root, some the leaves, others the seed. No wonder, then, that some difference of opinion should exist (as is the case with authors both ancient and modern), in estimating the real pretensions of any plant, when it is not always manifest which part of the plant has been the subject of investigation. Moreover, how great soever the virtues of a plant may be, want of skill in the manner of preparing or extracting its properties may render them inert, or the plant may have been collected at an improper season.

When it is considered that the use of foreign drugs entails so heavy an addition to the expenditure of a practitioner, and how much he could be relieved by the substitution of indigenous remedies, wherever it could be done without injury to his patient, I trust it will not be necessary to offer any further apology for having drawn the attention of your readers to a subject important to society, as well as to the profession.

J. K. WALKER, M.D.

Huddersfield, May 10th, 1840.

CASE OF ATROPHY OF THE GALL BLADDER,

WITH OBLITERATION OF THE BILIARY DUCTS.

To the Editor of the Medical Gazette.

SIR,

If you consider the inclosed case of sufficient interest, will you do me the favour to give it a place in your valuable journal.—I am, sir,

Your obedient servant,

GEORGE CURSHAM, M.D.

5, Saville Row, May 21st, 1840.

I was requested to see a child of the name of Wall, of the age of about six weeks. The mother informed me that the infant had been jaundiced from its birth, the surface being generally of a deep yellow colour. The stools were habitually white, composed (she says) principally of curdled milk. The urine was constantly of a very high colour, and producing such deep stains on the linen, that they could not be removed by washing. It had frequent attacks of vomiting, especially after taking food.

I first saw the infant about a week before its death, when all the above symptoms were still present. The infant moreover was restless and agitated, had feverish symptoms, and there was slight tenderness under pressure at the epigastrium and right hypochondrium. It had become much emaciated, and compared to what it was at the time of its birth, the mother says, "its flesh is now quite flabby." About twelve hours before the child died, convulsions came on, and recurred frequently until its death.

Examination of the body after death.

—*Thorax*: No disease of the thoracic viscera; the lining membrane of both auricles, especially the right, was very deeply tinged of a yellow colour. *Abdomen*: Intestines generally very much distended with flatus. *Liver*: Was, I think, larger than ordinary when at this age, possessing a firmer texture, and on being incised presented that peculiar striated appearance which, by some pathologists, has been termed the "nutmeg liver." On searching for the gall bladder, I found its place occupied by a small cellular bag, not larger in diameter than a common-sized goose quill, and about an inch and a half in length. A small cellular cord passed from its extremity, going to a similar one coming from the fissure of the liver, and passing in the usual way, as the ductus communis, to the duodenum. On making an incision into the upper part of the small bag, which I considered as the remains of the gall bladder, and introducing a blow-pipe, I could readily inflate it; but no air passed into what I considered the cystic duct; nor, on careful examination, could I ascertain that the hepatic duct was at all pervious, or (as will readily be supposed) any portion of the common duct. The mucous coat of the stomach was covered with a pale-coloured tenacious mucus; its texture appeared healthy. The duodenum contained a small quantity of imperfectly-formed chymous matter, of a pale whitish colour, not at all tinged with bile. Its mucous coat, as well as that of the jejunum and ilium, presented no appearance of disease. The *Colon* contained a quantity of matter, consisting of a mixture of coagulated milk and mucus, of a somewhat darker colour than that found in the small intestines, but not at all tinged with bile. On cutting into the kidneys, there flowed

from the infundibula and pelvis of the organs, a considerable quantity of opaque green fluid; and on pressing the mamillary processes the same kind of fluid was made to exude. The head was not examined.

It is to be regretted that permission was not given to examine the brain in this case; but as there were no symptoms of disease in the head until twelve hours before the child died, I cannot think that death occurred from disease in that organ. In the examination of the other cavities, no morbid appearances were found, save the state of the liver and biliary ducts above described, and these, taken in conjunction with the symptoms present during life, lead to the conclusion that death took place from this cause.

From the experiments of Sir B. Brodie, many years ago, as well as those subsequently made by Mr. Mayo, an inference was drawn, that an interception to the flow of bile into the duodenum rendered the process of chylification imperfect; and the former observes, that in every well authenticated case of obliteration of the common duct from disease, great emaciation has been observed. Tiedemann and Gmelin, while admitting the influence of the bile in assisting digestion, conceive that it has not so large a share in the formation of chyle as had been attributed to it; and set down the following proposition as established by their experiments: "Nul doute que la bile ne doit être considérée en grande partie comme une matière excrémentielle dont la sécrétion tend principalement à maintenir le sang dans un état de combinaison qui lui permette de servir à nutrition dans les differens organes."

In either view of the case, emaciation (as in the present instance) might be expected to result; in the one, from imperfect chylification; in the other, from an impure condition of the blood, rendering it unfit for nutrition. Both agree in the effect produced, though differing as to the mode in which it is accomplished.

Dr. Elliotson, however, in his *Physiology*, mentions two cases of a similar nature, in which it appears no such consequences resulted. In the chapter on the uses of the bile, there is the following note: Dr. Blundell has notes of the cases of two infants, four or five months old, in whom the hepatic ducts

terminated blindly, so that no bile entered into the intestines, and the stools were white, like spermaceti, and the skin jaundiced. But the infants had grown rapidly, and thriven tolerably, notwithstanding. No account, however, is given of the symptoms under which they laboured, nor from what cause death at last took place, so that there are no means of forming an opinion what was the influence of the lesion in question.

In the sixth vol. of the "*Archives de Médecine*," Andral relates several cases of complete obliteration of the common duct; in one, death ensued from rupture of the gall bladder; in another, from rupture of the hepatic duct; in a third, (a case of chronic jaundice) there was obliteration of the common and cystic duct, with atrophy of the gall bladder and liver. The subjects of all these cases were adults. Mons. Andral considers the obliteration to have been caused by inflammation and consequent thickening of the parietes of the ducts, followed by their transformation into ligamentous cords. As, in the instance above related, there were found the remains both of the gall bladder and the ducts, I am inclined to look upon it as a case of obliteration from the same cause. Moreover, as the infant was jaundiced when born, and the state of the parts seems to forbid the supposition that the morbid changes occurred subsequent to birth, may it not be considered as an instance of disease occurring to the fœtus in utero? The case therefore may not be thought uninteresting, first, as contributing to the pathology of jaundice in infants; second, as an addition to the cases of intra-uterine disease; and third, as showing the injurious effects of a complete obstruction to the flow of bile into the intestinal canal.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Practical Observations on Various Subjects relating to Midwifery. By JAMES HAMILTON, M.D. F.R.S.E. Professor of Medicine and Midwifery, &c. in the University of Edinburgh. 2d Edition, revised and enlarged. Longman, 1840. 8vo. pp. 425.

WHILE the last sheets of this work were passing through the press, the well-

known and justly esteemed author died, after an illness of only a few weeks' duration. Lamenting (as we sincerely do) the loss of Dr. Hamilton, who had always evinced great zeal in his profession, both as a teacher and practitioner, we are gratified in being enabled to state that this second edition of his "Observations" had been minutely and carefully revised by him, before the beginning of his short but fatal attack; so that this work may be regarded as his complete and parting legacy to the profession. Dr. Hamilton's object in publishing this work was to record those deviations from the established modes of practice in several ordinary affections of women, which the experience of nearly half a century had led him to adopt and recommend.

Prolapsus of the uterus is the subject of the first chapter. It is generally supposed that the mechanical cause of prolapsus uteri consists in a relaxed state of the ligaments which support the uterus. It might have been expected that our improved knowledge of anatomy would have corrected this erroneous opinion, but, as a proof that it has not, we may refer to the works of almost every writer, in which we find the old doctrine is implicitly adopted. Gardien* and Osiander† are of the same opinion as Dr. H.: they deny that the broad and round ligaments support the uterus in situ, and assert that the true cause of prolapsus is the softening and relaxation of the membranes of the vagina and of the cellular tissue which unites them to the linings of the pelvis. The treatment ordinarily pursued in cases of prolapsus, consists, in incipient cases, of confinement to a horizontal posture; application of cold to the loins, external parts, and vagina; injection of styptic liquors into the vagina; use of tonics; and in cases of long standing, the employment also of pessaries. Dr. Hamilton first objects to the horizontal posture. "Although it immediately relieves the uneasy feelings of the patient, the author long ago ascertained that it tends not only to impair the general health, but to aggravate the disease, by increasing the relaxation of the natural supports of the womb; and daily experience

has established the validity of this opinion." He objects also to the use of astringent injections into the vagina, and avers, that of the numerous cases of chronic enlargement of the uterus which have fallen under his notice, by far the greater number had been "unequivocally occasioned" by their use. This opinion is, we think, too strongly expressed. The suspicion, indeed, might arise, that the mischief referred to might be owing to styptic injections, but how it could be known that they "unequivocally occasioned" it, we can scarcely imagine. Dr. Hamilton recommends vegetable preparations, or diluted chloride of lime, or soda, as the only safe injections. To the use of pessaries, too, Dr. H. strongly objects, and, upon the whole, we have no doubt justly, although we cannot but think he a little exaggerates the inconveniences arising from their proper employment. He did not succeed in some attempts he made either by the introduction of stimulating substances into the vagina, or by surgical operation, in producing a cohesion between the sides of the vagina for the purpose of supporting the uterus, and thus mechanically relieving prolapsus. Finding, from repeated experience, the little confidence that could be placed in the usual modes of treating prolapsus, Dr. H. at length discovered a mode of supporting the uterus; which he says (and we can confirm the fact) is both effectual and safe. It consists in the use of a T bandage and a well-adapted cushion, so placed upon the external parts as to retain the uterus *in situ*. This bandage is to be worn whenever the patient is out of bed, as long as any symptom of the disease is perceived. It effectually relieves the unpleasant feelings, while it enables the patient to take walking exercise.

Polypus excrescence of the uterus.—Upon this subject, we only think it necessary to observe, that Dr. Hamilton appears to be imperfectly acquainted with the modern opinions and practice of the French and English surgeons in the treatment of polypus of the uterus. He objects to the use of the knife, and prefers the ligature. Excision, however, is now *generally* preferred by the best English and continental surgeons, and the preference rests upon the best of all possible foundations—abundant experience. Sir Benjamin Brodie

* *Traité d'Accouchemens*, t. i. p. 178.

† Osiander, *Diss. de Fluxu Menstruo atque Uteri Prolapsu*. Gott. 1803, 4 c. tab.; and also, *Die Ursachen und Hülfsmittel der unregelmässigen und Schweren Geburten*, by Osiander. Zweite Auflage, 1833. B. 3. s. 130.

has several times removed large polypi by excision, with perfect success. We saw Mr. Arnott remove a polypus, at the Middlesex Hospital, which completely blocked up the vagina, and which was nearly as large as a double-fist. Little or no hæmorrhage followed, and the patient was well in less than a month*. In several cases we have ourselves adopted the same practice, and with like success. Dupuytren operated by excision in two hundred cases, and *only twice* met with hæmorrhage to any extent, and in both cases it was quickly arrested by plugging the vagina. Let it not be supposed that we are contending for the perfect abandonment of the use of the ligature: in some cases the use of the knife, or rather the bistoury or scissors, would be quite impossible; as, for example, when the polypus is situated high up, and is of small size.

Enlargement of the ovary.—Confining ourselves to the opinions and practice which originated with Dr. Hamilton, or which he particularly insisted upon, we pass over many interesting practical remarks which this section contains, as to the origin and progress of ovarian enlargements. We quite agree with Dr. H. as to the difficulty, at least, of distinguishing ovarian disease in the early stages; and we could add cases which have occurred in our own practice, which were considered as ovarian tumors, but which we have no doubt were similar to that he refers to, in which an accumulation of hardened feces in the caput cæcum coli might have been mistaken for disease of the ovary. In modern times, the most respectable part of the profession have considered diseases of the ovary to be incurable. Dr. Hamilton admits that there are many cases of enlargement of this organ which admit only of palliative treatment; "but he can prove, by many living witnesses, that cases now and then occur where the disease is curable, not merely in its early stages, but after it has acquired such a magnitude as to require tapping." The use of mercury is condemned. "Adverting to the effects of percussion and of pressure, in chronic rheumatism, and knowing the influence of the continued use of the muriate of lime in indolent glandular swellings, he was led to the trial of these means. He

advises, therefore, that moderate and equable pressure of the abdomen should be made by means of a suitable bandage; that the enlarged part should be subjected, twice a day, to gentle percussion, and that a course of small doses of muriate of lime should be continued for at least several months." If pain or tenderness was felt on pressure, the daily use of the warm-bath was added. Dr. Hamilton assures us that this plan has been attended with much success in several well-marked cases. That the muriate of lime may not injure the digestive functions, a small proportion of the tincture of calumbo should be added. The formula used by the author is one part of tr. of calumbo to seven parts of the solution of muriate of lime; and of this the patient is directed to take a drachm, properly diluted, twice a-day. In the more advanced degrees of the disease, tapping becomes necessary, but cases are related which confirm Dr. H. in his opinion that this operation is not safe till the sac has acquired a certain degree of distension. Extirpation of enlarged ovary by surgical operation is objected to.

Evidences or signs of human pregnancy.—Dr. Hamilton "undertakes to prove, that both in the early and in the latter months of pregnancy, there are invariable signs marking that condition of the system." This sentence affords a striking proof of the very positive manner in which Dr. Hamilton was in the habit (we say this with every possible feeling of respect) of stating his opinions, however strongly they might be opposed to the almost united experience of the profession; for there are few, if any, practitioners, we believe, who would not require to substitute the word "generally" for "invariable," before they would acquiesce in the author's assertion. If, in the wide range of medical science, there is any subject upon which it behoves us to be scrupulously cautious in not assuming a positive knowledge, or power of discrimination, which we do not always possess, it is upon the question of the existence or absence of pregnancy: for upon the accuracy of our opinions upon this point, not unfrequently depend the character of the woman, the claim to property, the proper treatment of disease, and, in criminal cases (as where a woman pleads pregnancy in bar of execution), the preservation or destruction

* MEDICAL GAZETTE, vol. xviii. p. 261.

of the unborn child. We would not willingly add to the difficulties with which this delicate and responsible question is sometimes surrounded. We do not deny, that, for all common practical purposes, our means of determining the existence of pregnancy are very generally sufficient to lead us to an accurate conclusion. But we must deprecate the dogmatic confidence assumed by Dr. Hamilton; and in proof that we are justified in so doing, we refer to the various and well-known works on obstetrical subjects and medical jurisprudence; almost every one of which contains examples (and some of them very lamentable ones) of the danger arising from placing *exclusive* confidence in any of the signs or symptoms of pregnancy, until the process is so far advanced as to admit of examination by the ballottement or the use of the stethoscope. Dr. H. "has no hesitation in asserting that there are two circumstances which invariably attend pregnancy during the early months—viz. suppression of the catamenia, and a perceptible change on the surface of the mamma surrounding the nipple." All the other symptoms of pregnancy "ought to be disregarded." Now, briefly, with respect to those two "invariable" symptoms; for the subject has been too frequently discussed to justify us in entering into it at much length. The general belief of the profession amounts to this: that the symptoms referred to by Dr. Hamilton afford strong presumptive evidence of the existence of pregnancy, but that they do not amount to such a demonstration of the fact as to justify a man in swearing to it in a court of justice. That the menses may continue to flow during pregnancy, or (to guard against a verbal dispute) that such a periodical discharge may appear that cannot be distinguished from the menses, is the prevailing opinion of the profession, and our personal experience has afforded us several opportunities of knowing that the opinion is well founded. The areola around the nipple, it is admitted, too, is a very strong presumptive proof, but it falls short of a proof positive; and we must venture to object to the manner in which Dr. H. dismisses the opinion of Denman, of the areola being formed, in many of the complaints which resemble pregnancy, by the assertion, that it is quite inconsistent "with the observation

of every modern practitioner." We, among others, believe, that a true areola is sometimes formed around the nipple in cases of uterine disease or disturbance, and we refer especially to dysmenorrhœa.* At the same time we perfectly agree with Montgomery, that much of the discrepancy of opinion on this subject has arisen from want of sufficient care in observing, and accuracy in describing, the essential characters of the true areola. The evidence of pregnancy in the latter months, upon which Dr. H. relies, is the "distinct sensation of the occasional movements of the infant." We agree with him, that this sensation may, "generally," be distinguished by an attentive practitioner; but let us not forget the certain fact, that sometimes no motions of the child can be felt, by either the mother or the practitioner, at any period of pregnancy; and that sometimes, too, the most experienced accoucheurs have felt confident of distinguishing the motions of the child when the patient was not pregnant. To give one example: Dewees†, in the case of a young lady, who had all the usual symptoms of pregnancy, "thought he distinctly perceived the motions of the fœtus;" but it was ascertained afterwards, that the size of the abdomen, &c. depended upon an accumulation of menstrual fluid in the uterus. We cannot refrain from hinting, that Dr. Hamilton's definition of "quickening," which, in common with most writers and practitioners, he regards as the "first sensation by the parent of the motion of the infant," is liable to doubt and dispute. Many good authorities incline to the opinion of the late Mr. Royston, that "quickening," as it is called, is produced by the impregnated uterus starting suddenly out of the pelvis into the abdominal cavity, and that it is altogether independent of any motion of the child‡.

Upon the often debated, and still debatable question, of the duration of human pregnancy, Dr. H. agrees with the majority of his brethren, that the ordinary term may be, and is occasionally protracted, but he does not think himself entitled to give a decided opinion as to

* Cyclopædia of Medicine, "Signs of Pregnancy," vol. iii. p. 473.

† Essays on several subjects connected with Midwifery, p. 337. Montgomery, also, loc. cit. p. 478.

‡ Lyall's Evidence on the Gardner Peerage cause, Note, p. 68-9.

the period to which that protraction may be extended.

On the Management of the first stage of Labour.—In this section we meet with opinions and practical advice that would fairly justify a much more extended notice than we can possibly give. By the first stage of labour Dr. H. means, "all that happens previous to the complete dilatation of the os uteri;" and, because certain evil consequences "may" sometimes follow from the protraction of this stage, Dr. H. thought himself justified to "advise his pupils to secure the termination of the first stage of labour within twelve or fourteen hours from its actual commencement." If the protraction arises from premature rupture of the membranes, or "natural toughness of the os uteri," bleeding or opiate clysters are recommended, according to the state of the patient. If the resistance to dilatation arises from an "undeveloped band of the cervix uteri," the same means are advised; and, "half an hour after the opiate, pressure on the resisting band with the point of the finger during each successive pain." If protraction of the first stage of labour "depends upon such a relaxation of all the parts lining the pelvis, that the undilated uterus is, during every pain, forced down upon the external parts," it is only necessary, by the application of two fingers to the edges of the os uteri, to retain the uterus *in situ* during every pain till the head of the infant pass into the vagina." But the practitioner is guarded against any attempt "at forcing open the os uteri." A few other remarks are made, as to the mode of managing other kinds of protraction of the first stage.

Upon the whole, it is our decided opinion, that, guarded as is the advice of Dr. Hamilton, with respect to the management of the first stage of labour, and safely and judiciously as he, no doubt, was in the habit of acting upon it, if practitioners in general are influenced by it, that much more mischief than good must result; and that it would be much safer for a teacher to inculcate the maxim of Denman, viz. "whether a short or a long time be required for the purpose of dilating the os uteri, it is the duty of the practitioner to abstain from interfering in this part of the process."* Perhaps Dr. Hamilton's opinions were a little overstated, and severely commented

upon, when the first edition of his "Observations" was published; but Dr. Collins*, and Dr. Murphy†, of Dublin, advocate, we think, much safer doctrines than those of Dr. Hamilton upon the subject in question. The author's remarks on the management of the second and third stages of labour claim no formal notice.

In cases of adherent placenta, we are advised by most writers to insinuate the fingers between the placenta and the uterus, and gradually and carefully peel off the former. Now it is not so easy as may be imagined to distinguish the edge of the placenta from the uterus itself; and besides, as Dr. H. very correctly suggests, "there is hazard of exciting inflammation on the surface of the uterus by the pressure of the fingers." The plan advised by the author is at once easier and safer. It consists in pressing upon the substance of the placenta with the expanded fingers, bringing its circumference towards its centre, and detaching leisurely and carefully all that can be separated by this manipulation.

On Laborious Labours.—In this section many good practical remarks are made, which claim the attention of young practitioners especially. Dr. H. very properly "holds it to be a doctrine replete with great danger, that passions of the mind do not interrupt the progress of a labour." We cordially agree with him that no man can practise midwifery, with safety to his patients, and comfort to himself, who does not use his utmost endeavours to soothe the feelings and encourage the hopes of the suffering woman, whatever may be her rank in life. With respect to the egot of rye, the author is of opinion that it "can act in no other way than by influencing the imagination, and that it possesses no superiority, in this respect, over any other medicine." So we are inclined to think, and we have given it in forty cases, but yet we state our opinion upon the subject with becoming deference to the at least plausible affirmative evidence of others, in favour of the power of this agent upon the action of the uterus. Dr. Hamilton's remarks upon the use of the forceps, and the management of cases of disproportion between the infant

* Observations on the artificial dilatation of the mouth of the Womb during labour, &c. By Dr. Collins. Dublin Journal, March, 1837.

† Inquiry into the management of the first stage of Labour. By Dr. Murphy. Dublin Journal, May, 1837.

* Denman's Midwifery. Waller's edit., p. 135.

and pelvis, are marked by sound practical judgment, and although a little severe upon the practice of others, his strictures are, we think, well founded. We do not doubt that in embryotomy the crotchet is "a more powerful means" than the craniotomy forceps, but we should always prefer the latter instrument, on account of its much greater safety. Dr. D. Davis's osteotomist is thought to be of little practical value. Dr. H. speaks from much experience upon the subject of inducing premature labour in appropriate cases. He first tried the effect of separating a portion of the decidua from the cervix uteri, without rupturing the membranes. This practice he recommends with confidence. Out of 77 cases of premature labour, artificially induced by the previous rupture of the membranes, 33 infants were born alive. Of 58 similar cases, the membranes having been preserved entire, 51 were born alive. By the former practice, less than one-half of the children being saved; by the latter, more than seven-eighths were born alive. Thus then, are the objections of Velpeau* to Dr. H.'s operation, satisfactorily answered. In the management of preternatural labours, Dr. H. says that the first object is to determine how the infant can be best adapted to the pelvic passage. The prevailing doctrine is, that the fore part of the fœtus should be turned to the back of the mother. He agrees with Baudelocque, however, and evidently with sufficient reason, that in every case where the feet are brought down, the toes should in the progress of extraction be turned into such a position, that the belly, the breast, and the face, shall be made to pass in succession along the nearer sacro-iliac synchondrosis. As a general rule, we doubt the propriety of hastening the delivery of the child in footling cases, in the manner recommended by the author. By the plan proposed, the lives of more children may, no doubt, be saved; but we should fear for the safety of the mother. Dr. Denman's opinions upon the subject of spontaneous evolution scarcely required that Dr. H. should have raised "his warning voice" against practitioners being misled by their opinions. Denman has been misunderstood and misrepresented by many

others besides Dr. Hamilton, upon this point. A reference to the 1st and 2nd papers, published by Dr. Denman, in 1785;* to the 1st edition of his midwifery, in 1795; and the 7th edit. by Waller, will show that he went no further than to state, that the knowledge of the occasional occurrence of spontaneous evolution, (as it is called) might be some relief to the practitioner's mind, and prevent him from having recourse to hazardous operations, in those cases where turning either cannot be effected without danger, or where it is impracticable. Velpeau†, Blundell‡, Gooch§, &c., have also mistaken Dr. Denman's opinions upon this subject. We differ entirely from Dr. Hamilton, in his condemnation of the use of the plug in cases of uterine hemorrhage, in the latter months of pregnancy. His "important objection to the practice is, that from the condition of the uterus, after the seventh month of pregnancy, the blood discharged by the separation of the placenta, if prevented from passing per vaginam, may accumulate within the cavity of the uterus, and prove fatal." This is an oft-repeated and plausible objection to the practice of plugging the vagina in cases of hemorrhage; but it is nearly, if not entirely, an unfounded one; and let it be remembered, that even if cases had occurred of this accumulation of blood within the uterus, when the external flow was prevented, we should not be justified in abandoning the practice. Our means of arresting severe and fearful uterine hemorrhage are few, and none too certain; and we cannot resign that which we, in common with the majority of the most experienced practitioners of Europe, consider the most efficient, because it is liable to occasional failure. Even the possibility of the "important objection" advanced by Dr. Hamilton, is denied by many good authorities, as Dewees||, La Chapelle¶, Legouais**, &c. La Chapelle, certainly one of the ablest and most experienced practitioners in Europe, states that no such accident ever occurred at La Maternité, and that "le tamponnement†† est le seul moyen

qui puisse empêcher la femme de succomber immédiatement à la perte de son sang, quand l'état des parties rend inadmissibles toute tentative d'accouchement artificiel." Again too, we differ from Dr Hamilton in his condemnation of rupturing the membranes, as a means of arresting uterine hemorrhage. It is true that the discharge of the liquor amnii "may fail to check the hemorrhage;" but we cannot admit the second objection, "that it must increase both the difficulty and the danger of turning, should the agency of the case eventually require that expedient," because if such difficulty were created to the operation of turning, the hemorrhage would, almost to a certainty, be arrested. But upon this subject, as upon several others, Dr. H. appears to regard his speculative opinions to be of equal weight with the contrary opinions of the best practitioners, which are founded upon extensive experience. "During the last thirty years, the author has only met with two cases where he adopted this practice"—of rupturing the membranes. Not unnecessarily to accumulate evidence, we shall mention but two opinions, in which we perfectly coincide. Gooch* says that in his practice, hemorrhage never continued after the rupture of the membranes. Rigby† supports the practice by more than 60 cases. We think, with Dr. Hamilton, that the hitherto published evidence upon the subject of transfusion, in cases of alarming effects from hemorrhage, is, at least, very equivocal.

Convulsions during Pregnancy and Labour.—The author attributes his success, in the treatment of this always frightful and too frequently alarming disease, "entirely to the large bleedings" he adopted. He never directed less than about fifty ounces, by weight, to be drawn at first, "and if there were not a decided improvement within the hour," he advised the same quantity to be again subtracted. And further, "experience has taught him, in directing the first bleeding, to disregard peculiarity of constitution, for the most delicate persons require the same quantity to be subtracted as the most robust." We scarcely think it necessary to guard our readers against such a use of the lancet, without reference to the con-

stitution of the patient. We believe that such enormous bleedings can rarely be indicated, and can as rarely be justifiable. Upon this subject we may observe, that Dr. Collins, of Dublin, suggests, we believe, a novel and plausible mode of practice; viz., to keep the patient under the nauseating influence of tartar emetic after the first bleeding, and free purging with calomel and jalap. The volume concludes with a few brief remarks upon topics of comparatively minor practical importance to those which we have felt it incumbent to dwell upon.

In conclusion, we cannot refrain from remarking, that Dr. Hamilton's work is not exactly one we should place in the hands of a student of midwifery, although we admit that a well-informed practitioner, who is prepared to judge for himself, and to modify many of Dr. H.'s opinions by his knowledge of the best opinions of the day, may derive from it much useful instruction. An anonymous writer cannot fear the charge of plagiarism, but for the honour of the GAZETTE, we must observe, that if perchance any of our readers should detect a similarity of opinion, or the same tone of critical comment, in this notice, and that contained in another journal, that this is not the first time or place in which the present reviewer has performed the duty he now concludes, with the sincerest feeling of respect for the memory of Dr. Hamilton.

Specimen pathologiæ generalis veterum Græcorum. Scripsit SOPHOCLES AB ECONOMUS [ECONOMO], Dr. Medicin. et Chirurg. Berolini, 1833.

A specimen of the general Pathology of the ancient Greeks. By Dr. SOPHOCLES ECONOMUS. 8vo. Pp. 165.

THIS very learned treatise is the production of a young Greek, Dr. Σοφοκλῆς ὁ ἐξ Ὀικονόμων; and is a cento of the opinions of the ancient Greek physicians in physiology and symptomatology. It is always curious, often interesting, and sometimes instructive. We regret, however, that the author has not furnished his work with an index, or table of contents; for these appendages, which are always useful, become absolutely necessary in a book of this kind, which is to be consulted rather than to be read. The following passage may give our readers

* Midwifery, 257.

† On Uterine Hemorrhage.

some notion of the manner of this literary mosaic :—

“The quantity of blood may vary in two ways, by being either too great or too small. The augmentation in quantity may be twofold, either as regards the strength or the capacity of the vessels.^a Copious nutriment generally causes an abundance of blood.^b But when this abundance exists, the memory is dulled,^c convulsions arise,^d burning fevers break forth,^e and the arterial pulse is altered.^f

“When there is a plethora of blood with reference to the patient’s strength, it corrupts the humours, and sends a flux to the weaker parts;^g this kind of plethora arises from heat, anger, and fever.^h But a plethora of the vessels distendsⁱ and sometimes bursts them, producing death by obstruction of these strainers of the body.^j When the arteries are obstructed by blood, the body soon loses sensation and motion, the vital force beginning to be suffocated; wherefore Hippocrates has said, that in those who are suddenly struck dumb, this symptom arises from repletion of the arteries.”^k [This is a guess at the meaning of the original, which is here unintelligible: “quare Hippocrates dixit, qui derepente obmutuerit, arteriarum repletiones corpus lædunt.”]

“A deficiency of blood often occurs, whence the body becomes pale, and therefore Hippocrates places together the pale (*αχρόους*) and the exsanguine (*λειφάμους*).^l A deficiency of blood is caused by want of nourishment,^m wasting fevers,ⁿ &c.” (p. 39 40.)

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

UNION SURGEONS.

THE more we look into the late report of the Poor-Law Commissioners, the more reason we see to deplore the oppression to which the Union surgeons are subjected. Complaints, whose justice is obvious, are heard from every part of England. In Devonshire and Cornwall, says Mr. Gilbert, “as regards remuneration, the general complaint from the medical men is that it is not sufficient*.”

Mr. Weale, who supervises parts of Beds, Bucks, Herts, Northampton, and Warwick, informs us, that, in the Newport Pagnell Union, the medical officers have complained of the inadequacy of the remuneration; he believes, that in the Towcester Union the medical officers have sometimes complained of the same thing; and says, that in the Walsall Union there is “a little grumbling with one—he who receives the greatest sum for his labours, and who would do so if he had more given.” No doubt he would, the cormorant! We make no question that he would take 100*l.* per annum—if he could get it. This reproof comes very pleasantly from an assistant-commissioner, with his comfortable wage of 1500*l.* a year. It reminds us of that scene in the *Duenna*, where Father Paul, after emptying his goblet, gives it to the starveling lay-brother; and on the latter endeavouring, but in vain, to suck out a drop, the lusty monk exclaims, “So, you sinful wretch, if there had been anything in it you would have drunk it!”

There is dissatisfaction in the Wol-

* Report, p. 169.

verhampton Union, "the present medical officers having presented a memorial soliciting payment by the case; which request the Board of Guardians have not seen fit to accede to."

In the Bromsgrove district of the Union of the same name, the medical officer's salary has been increased from 70*l.* to 90*l.* a year. In the Leighton-Buzzard Union, there would seem to be only one medical officer; he was originally engaged at 200*l.* a year, but this sum proving insufficient, it was raised, with the sanction of the Commissioners, to 230*l.* "*The time of the medical officer is devoted exclusively to the business of the Union, and he is not allowed private practice.*"

The Leighton-Buzzard district "is 55 square miles, extending in one direction eight miles from the surgeon's house" *.

It would be curious to ascertain how many hundreds or thousands of patients this devoted practitioner may have annually, and how much (if any) of his salary remains in his pocket when his drug-bill is paid. He has the advantage, however, of improving in the practice of medicine, and the arrangement is probably more satisfactory, both for him and the poor, than the ordinary method. It is clear, nevertheless, that he is worse off than the resident apothecary of a Dispensary, with a salary of sixty pounds.

Mr. Tuffnell answers for Kent and Sussex. In the East Ashford, Bridge, Gravesend and Milton, Malling, Tonbridge, Eastbourn, Hailsham, Lewes, and Ticehurst Unions, the medical officers are dissatisfied with their remuneration. In the Bromley Union, says Mr. Tuffnell, there is no dissatisfaction as to the medical arrangements; "but an application has been made by the medical officer for an increase of remuneration,

which is now (April, 1839) under the consideration of the Board." And in the Thakeham Union, one medical officer is discontented both "as to the amount of remuneration, and as to the *tender* mode of election." On the other hand, in the Isle of Thanet Union, the Guardians "considering the salary for attending at the workhouse much too large, have resolved to reduce it by £30."

It would be gratifying a liberal curiosity if Mr. Tuffnell would inform us what this salary is, which seems so large in the Isle of Thanet; is it £120 a-year? or even less than that? In the whole volume before us there is only one instance where the surgeon seems really to have got a small prize, and that is in the Penrith Union, where according to James Shaw, the clerk, one officer will have received £25 for a year, in which he had only one trifling case.* This is the single prize in a medical lottery of a thousand blanks, and clearly depended on some peculiarity of circumstances which the writer has not explained. The mere discontent of the Guardians at the amount of a surgeon's remuneration is by no means a *prima facie* evidence that it is either exorbitant or sufficient; for the constant underpayment of medical officers has habituated those who pay the salary, as well as those who receive it, to a scale far below any approximation to justice. At p. 273, for instance, Col. Wade, one of the Assistant-Commissioners, speaks with disapproving wonder of a Union, where "the medical expenditure for the current year has been increased from £700 to £1200! at 11*d.* per head on the population." This rate of eleven-pence a head seems to the frugal Colonel the very height of extravagance: let us soberly calculate if it be so, really. The British Medical Association propose, reasonably enough, that the average population of

* Communication from the British Medical Association, in Report, p. 281.

* Report, p. 211.

medical districts should be 2500; at 11d. per head, such a district would produce its surgeon £115 per annum; a sum which though it makes the military economist stand aghast, does not strike us as so eminently regal.

On the important point of medical relief, the fautors of the new act may be divided into two principal classes. The one consists of stark-mad Malthusians, who would rather be mortified by the Union surgeons performing their duties with great diligence, as this would put off the millennium of no-relief, and frustrate the attempt to worry the poor into penny clubs.*

The second class is made up of those who have no strong objection to the relief of the sick poor, provided it can be procured for nothing, or next to nothing. The cry of Union surgeons for real salaries, instead of sham ones, seems to them quite preposterous. They would scarcely object to the officers prescribing mutton and porter for the diseased and starving, were it not that they cost something. Like the Harpagon of Molière, they have no positive hostility to the good cheer; but only the price of it. "Que diable! toujours de l'argent! Il semble qu'ils n'aient rien autre chose à dire; de l'argent! de l'argent! de l'argent! Ah! ils n'ont que ce mot à la bouche, de l'argent! Toujours parler d'argent! Voilà leur épée de chevet, de l'argent!"* In the present volume there is a report by Mr. Tufnell, on the education of pauper children, in which he gives numerous instances of the astounding ignorance of the workhouse schoolmasters; but shrinks from the natural remedy, that of having a tolerable master in each union, as too expensive. His proposal, therefore, is to unite the

children of many Unions into one big central school, where they are to be made very perfect at the smallest possible cost. As to the objection founded on the cruelty of the thing, on the hardship of depriving the indigent inmates of a workhouse of their last remaining consolation, by the removal of their children, our readers may easily imagine that it is treated with sufficient disdain. Such an objection, indeed, could only proceed from minds quite ignorant of the principle of population, the philosophy of destitution, and the certain method of dispauperizing the community!

To return to the Union surgeons: Sir John Walsham, who is the viceroy of Northumberland, Cumberland, Westmoreland, Durham, &c., speaks of the dissatisfaction of the medical officers with the remuneration in the Hexham Union; and in the Houghton-le-spring Union the guardians actually offered salaries so minute, that they were thought too small by the Commissioners and Sir J. Walsham! Why are not these salaries set before us in figures? The numerical method grows in favour daily, and these Houghton-le-Spring offers would be a contribution to what we should call, in modern phrase, the statistics of shabbiness. It is to be observed, too, that practitioners were found to accept them.

In Mr. Day's district, Salop and North Wales, the discontent of the medical officers with the amount of remuneration is very frequent. In the Carnarvon Union, we are told that "dissatisfaction exists very generally in the Carnarvon district of this Union; some of the parishes being beyond the Menai, cannot be reached in stormy weather. The medical officers are dissatisfied with the rate of remuneration, and the poor complain of a want of proper medical attendance." Sir Edmund Head answers for Gloucester, Hereford, &c. In several instances the surgeons complain of the

* This happy era of untended sickness may arrive very soon if the humane do not keep up what Mr. Tufnell calls the "outcry." "I agree in opinion," says Col. Wade, "with those who would gradually withdraw medical relief from the lower orders."—Report, p. 255.

† *L'Avare*, Acte iii., Scène 5.

insufficiency of their salaries, and in others the districts are thought too large. Mr. Clive, who is assistant-commissioner for Norfolk and Suffolk, is adverse both to the poor and to the surgeons. He thinks that "medical relief is the connecting link between independence and pauperism," and fancies that the salaries of the surgeons would be sufficient, if orders were not given so profusely. (p. 238.)

So that a poor cottager, after lavishing his health and strength in creating wealth for his employers, is to be left to his penny club for medical attendance. But suppose he does not belong to a club? Why, then, he must go into debt with any surgeon willing to trust him; and the calculation how many years it will take to pay a bill of 3*l.* 7*s.* 9*d.* with the savings out of nine shillings a week, will be a fine cordial in his nervous fever. Or, what do you think of the loan system, gentle reader? Perhaps you never heard of it: it is as follows:—The guardians are empowered, under the new act, (that blessing in disguise,) to give relief to the sick poor, and afterwards recover the amount by attaching the wages in the hands of their masters. This "relief by loan," is Col. Wade's hobby; he thinks that, in conjunction with contracts per case, it is admirably adapted to lead to the total withdrawal of medical relief. The loan system, however, must be "of easy application." But, alas! he is obliged to confess that, as far as his own experience goes, no part of the law has worked so ill as that relating to the recovery of loans. The thought of such a process as attaching the wages of an underpaid and underfed labourer for a parish debt, fills every decent person with disgust; and, accordingly, there is a universal conspiracy against the law. Farmers, guardians, officers, and auditors, all set their faces against this bright scheme to take bread from the hungry;

and, worst of all, there is even a "reluctance of the magistrates to lend their assistance;" so that one of the prettiest clauses in the whole act is little better than waste paper. It would appear that two hundred and forty years of public charity have not been without effect on the tone of public feeling, and that Englishmen are not yet ready to go all lengths against the poor. This will require much time, and many more reports. *Nemo repente fuit Malthusius.*

DR. CAPE.

ST. THOMAS'S HOSPITAL.

At a meeting of the students of St. Thomas's Hospital, which was held on Tuesday, May 19, 1840, it was unanimously resolved—"That a letter be addressed to Dr. Cape, expressing the great dissatisfaction entertained by this meeting with regard to certain articles, calculated to prejudice his character as a teacher, which have appeared in the *Lancet* and other periodicals of last week; and to assure him of their continued confidence, respect, and esteem.

"2dly. That the chairman be requested to transmit a copy of this resolution to Dr. Cape, the *MEDICAL GAZETTE*, and the *Lancet*."

(Signed) CHAS. W. KENT, Chairman,
and forty of the Students.

In conformity with the above resolutions, the following letter was sent to Dr. Cape:

SIR,

I HAVE the honor to transmit to you the resolutions unanimously agreed upon at a Meeting of the Pupils of St. Thomas's Hospital on Tuesday last, and respectfully to express to you their high approval of the line of conduct which you thought it your duty to pursue during the contention to which these resolutions refer; which course they feel convinced tended both to the honor of the school and dignity of the chair of midwifery,

I beg to assure you that so far from their confidence and esteem being in the least diminished, the manner in which you have acted in this affair has greatly contributed to the increase of both.

I remain, sir,

Yours respectfully,

CHARLES WELLINGTON KENT.

1, Duke Street, London Bridge,
May 20, 1840.

ROYAL COLLEGE OF SURGEONS IN LONDON.

THE President and Council have great pleasure in announcing to their Members, that three Studentships in Human and Comparative Anatomy have been instituted by the College, to be held respectively for the term of Three Years, with the annual stipend of One Hundred Pounds attached to each Studentship; and that, at the instance of the Director-General of the Medical Department of the Army, the Physician-General of the Royal Navy, and of the Chairman of the Honourable East India Company, the General Commanding the Army in Chief, the Lords Commissioners of the Admiralty, and the Court of Directors, have, with the view of promoting the objects of the College, been pleased to place at the disposal of the President and Council an Assistant-Surgeony, in each service, once in three years, for such of the said Students as may be considered worthy of these honourable distinctions.

The President and Council have also the pleasure to announce, that, with the view of rendering the prizes granted by the College more worthy of competition amongst their younger members, they have augmented the Collegial (Triennial) Anatomical Prize from thirty to fifty guineas; and have added ten guineas to the like sum, allotted by its founder, to the Jacksonian (Annual) Surgical Prize.

(By order) EDMUND BELFOUR,

Secretary.

nosis.*

THE ULNA.

Fracture of the ulna is more rarely seen than that of the radius; but, like it, the fracture is usually seated near the inferior extremity of the bone, where it is thin and superficial: it may, however, affect the olecranon and coronoid process. When it affects the body of the bone, it is almost always direct, and produced by a fall, in which the bone has come against some angular body, and there is usually little displacement. The inferior fragment is, it is said, drawn into contact with the radius by means of the pronator quadratus; the superior fragment, firmly connected by its hinge-like articulation with the humerus, remains in its ordinary position.

This fracture, whatever part of the shaft of the bone it occupies, is easily detected; all that is necessary is to pass the fingers along the border of the bone at the point of fracture, when we shall feel an inequality, caused by the projection of the superior extremity, and a depression, caused by the inclination of the inferior extremity

of the bone, towards the radius; add to this, mobility and crepitation, easily produced by grasping the two fragments, and moving them backwards and forwards, and we have the prominent signs of fractured ulna.

Treatment.—In reducing this fracture, we follow the same course as in the radius, except that, when the fracture is near its inferior extremity, in making extension, we incline the hand towards the radial side: the after apparatus is similar in principle to that of the radius

OLECRANON.

The ancients did not bestow much attention upon fractures of the olecranon; they have left very few remarks on the subject. Its situation particularly exposes it to injury, and its connections to violent muscular action; but the great majority of fractures are a consequence of direct injury—such as a fall on the elbow; still there are a few cases on record in which the fracture was occasioned by the violent contraction of the triceps in: throwing stones, for instance.

The fracture may affect any part of this process; may be simple or compound; may be transverse or oblique; with or without contusion or injury to the joint. When the fracture is transverse, there may be considerable displacement, occasioned by the triceps drawing up the superior fragment; at the same time, by the action of the flexor muscles, the arm assumes the semiflexed position, so that the inferior fragment is also removed. If the fracture be situated at the base of the process, the ligaments described and figured by Sir A. Cooper, which pass from the olecranon to the coronoid process on one side, and on the other to the coronary ligament of the radius, may prevent any displacement.

This fracture is usually easily detected: the patient has fallen or received a violent blow on the elbow, or the forearm has been

violently extended, and acute pain, with a crackling sensation, have been experienced at the part; the elbow is swelled and painful, the forearm is semiflexed, and cannot be extended. At the back of the elbow there is usually a depression, large enough to admit the point of the finger, limited above and below by the two extremities of the bone. When we extend the forearm, carrying the arm backwards, and push down the superior fragment, we may bring them into contact, cause the disappearance of the depression, and produce crepitation. If, however, the tumefaction be great, these things are not easily done; and there is then some danger of mistaking the accident for luxation.

Treatment.—To reduce it, the olecranon must be pushed down and maintained in that position; the inferior fragment is brought nearer by extending the forearm, but the extension should not be complete, or the fragments will only be in contact at their posterior surface, and an interval will be left between them anteriorly: the callus may then interfere with the motion of the joint. It is for this reason that many surgeons place the limb in a semiflexed position. The upper fragment must be kept down, which is not always easily done, because the triceps muscle glides under the apparatus which may be employed for the purpose, and carries the bone with it. After placing the limb in the position we have named, a bandage is rolled from the hand to just below the elbow; the olecranon is then pushed down towards the ulna, the bandage is rolled above it, and it is thus secured. Mayor's plan is simple: he keeps the arm extended.

Complete extension is certainly the position most favourable for bringing the fragments together, but it is with difficulty supported, and is apt to leave stiffness at the joint. Dupuytren and Sir A. Cooper advised the employment of this position. Camper, Desault, Earle, Boyer, prefer a slight flexion. Those who prefer extension have suggested means for maintaining reduced the superior fragment. Wardenburgh placed the arm in supination. Bottecher placed a kind of bracelet above the superior fragment, this bracelet being kept down by tapes attached to the base of the index finger. Feyter fixed the bracelet by means of a glove: in both, the arm was extended. Among those who object to extension, some prefer semiflexion, others flexion at an obtuse angle.

Seventy or eighty days are necessary for union by bone, but if so long persevered in, motion must be carefully impressed upon the joint, otherwise it is most probable ankylosis will be the consequence. This motion should not be deferred beyond the twentieth to the thirtieth day.

Fractures of the olecranon are not generally consolidated like other bones; the medium of union is commonly fibrous, that is, not because of any peculiarity of the bone, but because contact has not been properly maintained; this is proved by the experiments of Sir A. Cooper and Mr. Gulliver; but even if the union be fibrous, the limb loses little either in power or activity, the action of the triceps is transmitted through it like a tendon.

CORONOID PROCESS.

Once on the living and once on the dead, Sir A. Cooper saw fracture of the coronoid process. In the latter case the fracture was old, and the fragments were united by ligament; he inclines to the opinion that union would always be so obtained. In the former case, it was produced by a fall on the palm.

In this fracture, when the forearm is extended, the olecranon projects backwards, in consequence of the displacement of the ulna, but this disappears when the arm is semiflexed. In the treatment of this injury, the surgeon must bear in mind that a fibrous union is all he is likely to get, and he must endeavour to make the medium as thin as possible. For this purpose Sir A. Cooper advises flexion and perfect rest for three weeks.

CARPUS.

Fractures of the carpus are always produced by direct and violent injury, and the soft parts are usually severely damaged: these injuries are not often so great as to require amputation, but the consecutive effects are often very serious. In some cases, motion at the part is not interfered with, but in many, flexion and extension of the wrist are entirely lost; whilst in others, the flexor or extensor tendons become implicated in the cicatrix, following the wound, and motion is still further impeded. The symptoms which indicate the kind of injury which has happened, are deformity and crepitation, but the latter symptom is often wanting.

Treatment.—If there be no wound, the treatment consists in the application of such an apparatus as is used in fractures of the forearm, the apparatus being, in the cases we are considering, extended to the hand. If the injury to the soft parts be great, this must be particularly attended to, and if the bones be shattered, we must to some extent put out of sight the question of reduction, and occupy ourselves with extracting spiculae, relieving tension by incision, if necessary, and endeavour to prevent the development of severe inflammatory action at the point; and the most complete immobility must be maintained.

METACARPAL BONES.

Fractures of the metacarpal bones are not

very frequently seen, because these bones support each other in resisting violence; the fifth suffers more frequently than the others; but if the first did not by its mobility escape the action of the causes of fracture, it is likely it would be oftener fractured than any. They are produced by gun shot, by wheels passing over the hand, or by other direct violence; they have been fractured by a fall on the extended hand. They may be simple or complicated, and the displacement is usually not great. If reduction be necessary, extension is made by drawing at the corresponding finger, whilst counter-extension is made at the wrist; compresses are placed over the point, and upon them, two narrow splints, one on the palmar, the other on the dorsal surface; consolidation is completed by the fourth week, but it is rarely free from deformity. If the fracture be a compound one, it may be necessary to relieve tension by incision, and to remove spiculæ of bone. If the fracture extend to several bones, and the injury to the soft parts be great, amputation is sometimes required. If the ordinary apparatus be found inconvenient, it may be found convenient not to extend the splints beyond the first phalanx, leaving the last two free and flexed. I place a thick pad upon the fracture behind, and another in front, upon the head of the fractured bone, where it articulates with the first phalanx.

FINGERS.

Fractures of the phalanges of the fingers are always complicated by contusion, sometimes by wounds; the inferior fragment is displaced in the direction of the bone, in the sense of flexion. They are easily detected by the mobility of the fragments, crepitation, and by the deformity which results from the inclination forward of the inferior fragment. If simple, these fractures are comparatively unimportant; complicated with wounds or comminution, inflammatory or nervous accidents may result.

Treatment.—Reduction is generally easy, by means of extension and counter-extension; the finger may then be rolled, and two small splints, one on the dorsal, the other on the palmar surface, should be applied: when this is done, the bandage should be passed around the finger on each side of the injured one; they will thus form two lateral splints. Even when there is much complication, a cure will frequently be obtained: thus, when it is a question of a first or second phalanx, we should not lightly decide on amputation; we frequently save fingers where the connection with the living body is very small. The cure of a simple fracture of the phalanges has taken place in the fourth or fifth week; a compound fracture requires a longer treatment.

THE FEMUR.

Well as the thigh bone is surrounded by muscles, it is frequently the seat of fracture; this is accounted for by its great length, by its curvature, and by the considerable efforts it has to sustain, under a variety of circumstances. It may be fractured at different points, but its middle third and its neck suffer most frequently. In some instances, particularly in children, the fracture is transverse, in others it is oblique; and in the latter case reduction is less easily maintained, and the chances of deformity are greater than in the former. The fracture may be simple or comminuted, complicated by contusions, wounds, or other injuries.

We must consider separately fractures of the extremities, the shaft and the neck of the femur. The *shaft* of the femur may be fractured by direct and indirect violence, by a blow, by a wheel passing over it, or by a fall from a height. It is recognised by a sudden acute pain at the moment of the accident; the patient cannot move the injured limb, an unnatural mobility can be detected at some point, crepitation can generally be distinguished, and the limb is deformed; it is changed in length, in thickness, and in direction. In the greater number of cases there is displacement of the fragments, so that the limb is shorter than the sound one, and its bulk is increased in proportion to the shortening. In children, the muscles have less energy, and the displacement is usually not great. Usually, the inferior fragment alone is displaced, and glides upon the superior, which remains in its natural position.

The large muscles, which on the one part are attached to the pelvis, on the other to the lower part of the thigh, the patella, the tibia and fibula, are, to a certain extent, the cause of the shortening; the pelvis being their fixed point, they force upwards the inferior fragment. Of course the displacement may be increased by position in bed, or by other causes; the muscles become more irritated by this, and still further contract, so that the riding of the fragments is increased. Transverse fractures are less subject to displacement in the length of the limb, because the two fragments mutually sustain each other, but laterally they may suffer considerable displacement. Still the situation of the fracture has much influence upon the position of the bone; when it is below the lesser trochanter, between that point and the end of the upper third of the thigh, then the superior fragment, which, when the fracture is lower almost always retains its place, suffers a displacement outwards and forwards as much greater as the fragment is shorter; it yields to the action of the muscles attached to the lesser trochanter; the lower fragment being acted on in the

way we have just mentioned, so that the limb is much more deformed and shortened than in other cases. When the fracture is seated just above the condyles, the inferior fragment is drawn backwards by the action of the muscles of the calf, the projection is felt in the popliteal space, and the form of the knee is much changed.

The *prognosis* of fractures of the thigh is always unfavourable, to this extent, that it is extremely rare to obtain a cure perfectly free from deformity; but when the middle half of the bone is affected, the risk of this is least. However well imagined the means we may use, it is almost impossible to prevent riding where the fractured surface is oblique. Where there are complications, the prognosis is more unfavourable; probably the most dangerous complication is a gun-shot fracture, the ball passing through the thigh. The cases of cure under those circumstances are comparatively few.

Treatment.—Many modes of treatment are employed in cases of fractured thigh. In one the knee is flexed, and the limb laid on its side; in another, the leg and thigh are maintained, in a state of flexion, on a double-inclined plane; in a third, the limb is rigidly extended; in a fourth, the limb is suspended above the bed. In our own country, the two first methods, variously modified, have been commonly employed; the third is generally used in France; the last is the plan of Sauter and Mayor: it is not much used, but in complicated cases has many advantages.

Whatever may be the plan of treatment adopted, the first indication is to reduce the fracture, so that the length and direction of the limb may be natural; and, unless there be much irritation, to excite spasmodic action: this is generally easily done; and even when this action exists, a large bleeding, or nauseating doses of tartar emetic, will usually subdue it. In many cases even these means may be dispensed with, and yet the object be attained, by suddenly directing the patient's attention to some other subject. If difficulties arise, we may neutralise muscular action by simple extension, maintained until the muscles are tired: we may accomplish the object by semi flexion, or by associating with it traction. If we adopt the first plan, the patient is placed upon a bed; counter-extension is made by passing a well-padded band between the thighs, and securing it to the bed post, or to a ring in the wall; or by grasping the pelvis: the foot is grasped, and slow graduated extension made, first in the direction of the inferior fragment, then in that of the limb, until it has assumed its accustomed length and direction.

In considering particularly these modes of treatment, we shall begin with the semi-

flexed, which owes its celebrity to Pott. It seems evident that he mistook, or did not exactly comprehend, the advantages of the straight position, and that, in exaggerating the good of relaxing the muscles of the limb, he lost sight of the serious inconvenience of the semi-flexed position. We cannot place the limb in such a position as will relax all the muscles of a limb. There can be no question that it would be desirable to attain such a condition if possible; but what is the position in which these organs may be all equally relaxed?

No one can be ignorant of the fact, that if we bring nearer together the insertions of certain muscles, we produce tension of their antagonists. Pott recommended that the thigh should be laid on its outside; that the body should be inclined to the same side; that the leg should be semi-flexed, so that it, as well as the foot, should rest on the outside; a large, well-padded concave splint should be laid under the thigh, from the great trochanter to the knee; another splint is laid on the inner side, from the groin to the knee, and secured there by means of the eighteen-tailed bandage; and in this state the limb is left until the fracture is consolidated. Pott's plan was, to place the leg and foot on a higher level than the thigh; but this position forcibly rotates outwards the condyles of the femur. If the bed be a common one, the body is soon in a hole, and the leg too much raised. Samuel Cooper believes that this position is a frequent cause of deformity, the foot being inclined outwards after consolidation. In France, this method has found little favour: the objections raised are, the impossibility of comparing the two thighs, to ascertain whether consolidation is going on properly; the discomfort of the position when long continued; the pressure upon the great trochanter; the derangement occasioned by defecation; the difficulty of preventing movement in the limb; and the impossibility of employing it when both thighs are fractured.

Sir C. Bell's plan, as modified by Earle, has been a good deal used. The limb is placed on a double-inclined plane; a long splint is placed on its outside, from above the great trochanter to the knee; a corresponding splint is placed on the inner side, and the foot is sustained by a board. There can be no question that this kind of semi-flexion is borne much more easily than extension; the inferior fragment is less likely to rotate outwards; and, if the limb be properly fixed, sufficient extension may be made.

Dupuytren proposed another method, by which semi flexion was combined with extension. He formed a double-inclined plane with pillows; he so arranged it that the buttocks of the patient should not rest

on the bed; the limb was surrounded by a tail bandage; two splints extended from the pelvis to the knee; the leg was secured to the mattress; and being thus fixed, the pelvis, not resting on the bed, was making constant extension. This plan of Dupuytren's, however, is open to many obvious serious objections, which do not attach to the principle as carried out in the plans of Sir A. Cooper, Smith, Amesbury, Sauter, or Mayor.

Advantageous as this plan is by many conceived to be, it has not been much employed in France. They prefer the method indicated by Hippocrates, and practised by the Greeks—extension; and a feeling in its favour is increasing here. Many means have been used for keeping up extension; and of those, the method of Desault has been most extensively employed. An unyielding bed is prepared, and the patient is laid on it. Under the affected limb a piece of linen is placed; it must be as long as the limb, and wide enough to allow splints to be rolled up in it. Under this cloth a tail-bandage is placed from the upper part of the thigh to the foot. The splints must be two in number; one, outside, extending from the iliac spine to four inches below the foot, and the other, inside, from the tuberosity of the ischium to the foot: sometimes a third splint is placed in front, and extends from the groin to below the knee. Compresses are placed three-fourths around the thigh; three cushions separate the splints from the thigh; the whole is secured by five or six tapes or bandages. A bandage is then brought either around the pelvis, or between the thighs, and firmly fixed to the notch at the summit of the outside splint; the foot is firmly fixed to the inferior extremity of it, and the limb is sufficiently extended: by this means the lower fragment is kept down, the superior fragment is kept up. The apparatus is daily examined, and the bands tightened if necessary. Every eighth day up to the thirtieth the apparatus is removed to ascertain that the reduction is exactly maintained. By the fiftieth or sixtieth day consolidation is usually complete in the adult; in old persons not so soon; in chil-

dren by the fortieth. Before the apparatus is removed it is necessary to ascertain that there is solid union; if it be so, the limb should be surrounded by a roller to prevent œdema, but the patient should not get up for three or four days, and when he begins to use the limb it should be cautiously done. Such was the apparatus of Desault, which completely accomplished his wishes—to make the foot, the leg, the thigh, and the pelvis, a whole.

However well applied the apparatus may have been, if the fracture be very oblique, the fragments may ride, and the shortening may be considerable. To obviate this shortening, many surgeons employ continued active extension, and this is variously applied. Extension was made by the Arabs, by attaching two bands to the knee or foot, fastening to their other extremity a weight, which is carried over the foot of the bed, and constantly dragging upon the limb. Counter extension was made by passing a band between the thighs and fastening it the head of the bed. Active extension has also been made by means of sliding splints.

The modifications made by Boyer in Desault's plan are not great; and the modifications more recently made in the long splints in no wise improve the principle so steadily kept in view by Desault, though in detail they offer considerable advantages. Of these the simplest and most effective I know is that used by Dzondi, Gibson, Nicolai, and Liston. It consists of "a deal board, of a hand's-breadth for an adult. It should extend from opposite the nipple to three, four, or five inches below the sole of the foot; it is perforated at the upper end by two large holes, and fastened by two deep notches at its other extremity. A sufficient hollow or perforation is made opposite the ankle, a pad of corresponding breadth is attached by a few pieces of tape; a roller is split at the end, and then tied through the openings in the top part of the splint, unrolled so far, and fixed for the time to the lower end of the pad. The apparatus, thus prepared, is here represented, before and after application.

Figs. 1 and 2.

"The reduction accomplished, and the position preserved by an assistant placing one hand over the dorsum of the foot, and the other upon the knee, a narrow roller is turned from the toes to a little below the fracture, with moderate firmness, to prevent œdema; a perineal band, consisting of a large soft handkerchief, or shawl, with some tow or wadding rolled in it, is placed under the patient. The splint is then laid along the outside of the limb; the roller, already spoken of, is passed under the sole of the foot, and turned around the ankle and heel, previously well padded, to prevent the painful effects of pressure. The roller is repeatedly carried through the notches as it is crossed over the dorsum of the foot, and alternately turned round the limb to near the groin. The apparatus is thus prevented slipping upwards. The ends of the band are passed through the perforations, drawn with moderate tightness, and firmly tied. A few turns of a broad bandage around the pelvis and chest complete the proceeding. The perineal band by which the splint, and with it the limb, is pushed downwards, is attended to from day to day, and tightened as it becomes relaxed, in order to overcome any tendency to shortening." (Liston.)

But the injury the limb has sustained may prevent the use of this apparatus, and then the double-inclined plane, or some other machine, may be necessary. Still, whichever may be employed, intolerable pain will sometimes be occasioned, as well as deep sloughs; therefore it is prudent to see the patient daily, either to tighten or to relax the bandages when the constriction causes severe pain.

In Germany, the plaster of Paris plan has been much employed, and in many cases I strongly support its usefulness; but I have not had sufficiently numerous opportunities of testing it to speak from experience on the subject. The thigh be-

ing fractured, the patient being placed on a bed, the fracture is reduced, and the limb being surrounded by a flannel roller, all that is necessary is to provide a box of the length of the limb, and about an inch wider and deeper than the thigh. The fracture is reduced, the limb is placed in the box, and fairly extended, or placed in a convenient semi-flexed position; semi-fluid plaster is poured upon it until the thigh part of the box is filled. It is so held for a period not exceeding half an hour; when the plaster will be set, displacement will be impossible, and no partial pressure can occur.

As to the immoveable apparatus employed by Larrey, I object to it as a general plan of treatment, because it puts difficulties in the way of ascertaining, from time to time, whether the fragments are in their proper position, and what is the condition of the limb; but at present, the plan has been so much improved upon by Seutin and others, that I think it should be fairly tested in fractures of the thigh, as it has been in those of the arm and leg in this country. It appears, that, within M. Sauter's knowledge, it has been applied, in the low countries, in no less than 28 cases, with such success "that in eleven of them there was no shortening or deformity." Now although I am not so sanguine as to expect such a result as that, I think there are many cases, especially those of children, in which the plan may be found decidedly useful.

The plan of Sauter and Mayor, already shewn, has been a good deal employed by the inventors, and in cases of great complication may occasionally be found useful, especially where irrigation is advisable. At present, Mayor has substituted iron wire for the board, and it is found that it accommodates itself comfortably to the limb, and facilitates the escape of any lotions which may be used. In young

Fig. 3.

children, fractures of the femur, whatever may be their direction, are much more easily reduced and maintained so than in adults, and the chances of shortening are less. In them, all that is necessary after reduction is to roll the limb from the foot to the groin, to place before, behind, and on either side of the thigh and leg, light splints of wood or milled board, and to fix them there with a bandage.

Such are the principal means invented for the purpose of preventing displacement in fracture of the shaft of the femur: some of them were specially destined for that of the neck, but as they can be indifferently employed in those of the shaft, it was necessary to allude to them here. Looking at them generally, it is evident that, except in young children or very debilitated persons, simple bandaging or position is insufficient. The method of Pott

is too fatiguing, and too likely to produce displacement; but certainly the modifications of it, introduced by Bell, Earle, Amesbury, and others, have much lessened those drawbacks; still, if shortening can be prevented by any means, I do not think this plan capable of effecting it. If extension be associated with it, the shortening will be often very trifling. This is best accomplished by placing the patient on his back, with the limb semiflexed over any apparatus, with a collar just above the knee to which the extending power is applied. This may be accomplished by the machines of Earle, of Santer, or of Amesbury. In the application of semiflexion, be careful that the thigh piece is long enough to prevent riding of the fragments: the effect of this is shewn in fig. 4. If this be neglected, all the evils of exaggerated muscular action

Fig. 4

will be realized in a plan whose principal recommendation is to avoid that circumstance. The plan of complete extension is, unquestionably, one of great value, much employed on the continent, but less favourably regarded in our own country, though, even here, a feeling in its favour is gradually extending. The tendency to shortening and deformity is more certainly avoided by this plan than by any other; its inconveniences, I believe, are, that forced extension is a more painful position than flexion, and that the pressure upon particular points is apt to produce sloughs. The immoveable system, variously modified, or the plaster of Paris plan, is compatible with either position, and may be, in many cases, advantageously associated with either.

INFERIOR EXTREMITY OF FEMUR.

Fracture of the inferior extremity of the femur may be seated just above the condyles—may extend between them, so as to separate one of them from the shaft: sometimes there is, at the same time, a vertical and transverse fracture, so that each condyle is separated from its fellow, and from the rest of the bone.

A fall on the knee, or external violence directly applied to this region, is the ordinary cause of this kind of fracture, which is often complicated by contusion of the knee, or wound of the soft parts.

When transverse, the inferior fragment may be drawn backwards by the action of the gastrocnemii muscles, and an unequal tumor, thus formed, is occasionally felt in the ham; in the vertical fragment, the separated condyle is moveable: sometimes the two condyles are removed from each other, so that the patella is depressed between them.

The vicinity of the knee, and the frequently great obliquity of the fracture, render the prognosis more serious than in fracture of the shaft. In the cases mentioned by Sir A. Cooper, there was considerable shortening and a forward projection of the superior fragment, by which the patella was displaced, and there was much injury to motion at the knee-joint.

The tendency to draw backwards the inferior fragment is the circumstance to which most attention has been directed. To prevent it, the partisans of extension have advised that a pad should be placed in the ham; those who prefer semiflexion,

have found in the relaxation of the gastrocnemii an argument in favour of their plan. But my own opinion is, that the tendency to this kind of displacement is exaggerated: in Sir A. Cooper's three cases there is no mention made of it, though there was considerable shortening.

Treatment.—In the treatment of transverse fracture above the condyles, I would advise that the semiflexed position should be used; not so much because I apprehend the occurrence of this displacement, though, if it occur, unquestionably it would be the most favourable position, but because I prefer it generally: besides, this tendency might be overcome by placing a cushion in the ham. The only objection I know to semiflexion is the chance of ankylosis as a consequence of injury to the joint; but this is unusual, and may be guarded against.

In transverse fracture and separation of the epiphyses, the extended position is supposed to answer best, "because the inferior fragment is forcibly pressed against the superior; a condition which is very advantageous for the formation of callus." But even then, special circumstances may oblige us to employ semiflexion. In that case we should, before the fortieth day, ascertain whether there be rigidity at the joint, as we can then enlarge the angle of the inclined plane to any extent. If a single condyle be detached, Sir A. Cooper advises that the limb should be extended—that a roller should be wound round the knee—that softened mill-board should surround the knee, and be fixed there by a roller. When this apparatus is dry, it is adapted to the shape of the knee, and maintains exact reduction of the fragment. Six weeks after accident we begin to move the joint, to prevent ankylosis. He mentions a case of compound fracture of the external condyle, in which a portion was extracted, and yet the case did perfectly well.

SEPARATION OF THE EPIPHYSES.

The epiphyses of the femur are usually united by bone about the twentieth year, and up to that time their separation is not uncommon. Bertrandi and Roux state that their patients could not stand, and there was circular ecchymosis at the point of separation of the epiphyses. The displacement in these cases is rarely great, and it can scarcely be confounded with any other injury than transverse fracture above the condyles; but as the separation of the epiphyses only happens in young persons, the chances of error are lessened; and even if it occur, no serious inconvenience is occasioned, for the treatment in both injuries is the same. The treatment of these cases is simple: reduction must be accom-

plished as quickly as possible, and this is best done during extension, which is the best position to be preserved, as in fracture of the inferior extremity of the femur.

SUPERIOR EXTREMITY OF THE FEMUR.

Fracture of the upper extremity of the femur may be situated at the base of the great trochanter, the neck, or immediately below the lesser trochanter.

Fracture of the *great trochanter* is usually the result of a violent shock received on this part; it has been produced by violent muscular contraction. The fracture may be transverse, or more or less oblique; in young persons it may be separated in the condition of an epiphysis, and then it is always transverse.

The symptoms are as follow:—If you grasp the trochanter between the finger and thumb, and rotate the femur, you find that the trochanter does not move with it, and during this time we may distinguish a crepitus; there is pain, and difficulty in moving, particularly in abduction. But all these signs may fail if the fibrous expansion of the middle and lesser glutei is not destroyed. Sir A. Cooper mentions a very striking example of such a fracture, observed by Mr. Key, and which was not detected till after death. Like fracture of the patella, the calcis, and the olecranon, the difficulty here is to keep the fragments in contact; in consequence of this, the medium of union is generally fibrous.

Fracture just *below the lesser trochanter* is produced by similar causes to those which fracture the shaft; but the injury is more serious, because of the great displacement of the superior fragment, and the little power we have of keeping it down. The psoas and iliacus muscles draw it forcibly forwards, so as to direct its inferior extremity towards the front of the thigh, whilst all the muscles inserted into the digital cavity of the great trochanter impress upon it a movement outwards. The inferior fragment, on the contrary, is carried upwards and inwards by the contraction of the adductors. The consequence of this is a deformed union, with an angular projection of the fragments towards the outside of the thigh, with shortening (as in fig. 5).

Though we may adapt to this fracture the different bandages we have alluded to, Sir A. Cooper recommends that the limb should be kept in such a position that the thigh may be forcibly flexed upon the pelvis, so as to relax the psoas and iliac muscles, and thus to lessen the tendency to the forward movement of the superior fragment. For this purpose, the knee must be raised on an inclined plane, whilst the patient will be so propped up as to be nearly in a sitting position. This eleva-

Fig. 5.

tion of the trunk should be carried, according to Cooper, to 45 degrees. Of course other means, such as splints and bandages, can be employed; but the tendency to deformity is seldom or never completely overcome.

NECK OF THE FEMUR.

Fracture of the neck of the femur is a subject which has excited as much attention as any in the whole range of medical science, yet the ancients appear to have confounded it with luxation, (*Salzmann de Luxatione ossis femoris rariore, frequentiore colli fractura*.) an accident much more rare than fracture of the neck. The discussions which have been raised on the question of the possibility of osseous union, on that of diagnosis, and the inventions for the purpose of preserving immoveable coaptation, are matters of great interest to every surgeon.

Though the very thick muscular cushion by which it is covered, and the projection of the great trochanter, might be supposed to render the occurrence of fracture as a consequence of direct injury comparatively unfrequent, yet the fact is not so; the most frequent cause of fracture of the neck of the femur is a fall on the great trochanter. In a great many cases, however, fracture is produced by *contre-coup*, by shocks impressed upon the foot, or the knee. Of 30 cases taken from the *Clinique de Desault*, 24 were consequences of falls on the trochanter. Sir A. Cooper mentions a case in which the fracture was produced by a sudden twisting of the trunk, the limb being fixed.

It ordinarily occurs in elderly persons, and the anatomical changes which are brought about in the neck of the femur to a certain extent explain the frequency of this fracture in persons advanced in life. Sir A. Cooper believes also that the more horizontal direction of the neck in woman, and the comparative feebleness of their

constitution, expose them more than men to this fracture. Sanson states that so large a proportion of these injuries as two-thirds occur in women.

Fracture of the neck may occur at its middle, where it is thinnest, at its superior extremity, near the head of the bone, or near its junction with the trochanter major, but the most important distinction relates to the capsule. It may be entirely within, or entirely without the capsule, or it may be partly within and partly without. An intra-capsular fracture is usually more or less completely perpendicular, and occurs where the neck is thinnest and most spongy; in a large number of cases the fracture is oblique, extending to a certain distance within and without the capsule. Sir B. Brodie saw a case in which the obliquity was so great, that the superior prevented the ascension of the inferior fragment, and there was no displacement or shortening. Extra-capsular fracture is seated near the base of the neck.

Symptoms.—The symptoms of fracture of the neck are sufficiently numerous and sufficiently marked to render the diagnosis easy. At the moment of the injury a severe pain is felt at the hip, and sometimes crackling is manifest; the patient cannot ordinarily move the thigh, and if he be down, he cannot usually get up: still many cases have occurred in which the patient has not only been able to get up but to walk home. Boyer mentions the case of a man who with the assistance of a stick walked about, some days, before displacement became evident. Many similar cases are on record: this can only be explained by assuming, with Eckl, that the fragments dovetailed one with the other.

The injured limb is almost constantly shorter than that of the sound side, but the shortening is less when the fracture is within the capsule than when it is outside of it; this is owing to the capsular ligament preventing great displacement. Sir A. Cooper does not, however, think this by any means general, and that probably it is more a theoretical than a practical point. If there be strong reason for suspecting fracture, and shortening cannot be made out, Sir A. Cooper recommends that the patient should stand up, to ascertain if the heel touches the ground; if it do not, and we try to make it touch, a pain is manifested at the hip, which seems to be owing to the dragging of the *psaos iliacus* and *obturator* muscles; the shortening is owing to the contraction of the muscles by which the inferior fragment is drawn upwards. If we ask the patient to raise the whole limb while lying on a bed, he cannot do it. If we use slight traction upon the limb, the shortening disappears, but as soon as we cease to make extension, it re-

appears. The knee is slightly flexed and rotated outwards. The trochanter major is less prominent, and nearer to the crest of the ilium than that of the other side. The corresponding buttock is more prominent than the other. The movements which we impress upon the limb give acute pain at the hip and the groin. Flexion of the thigh is painful; less if we incline it inwards than outwards. During the time we are moving the limb crepitation can often be heard, but this is not constant. Sanson proposed a plan which he had rarely known to fail; with one hand he takes hold of the leg just below the knee, flexes it upon the thigh, raises the thigh until it is at a right angle with the pelvis: the muscles being thus relaxed, he impresses upon the limb a movement of rotation, then alternately moves it backwards and forwards, whilst with the other hand he grasps the great trochanter, and assists in this backward and forward movement. If during these movements no crepitation is produced, if the shocks impressed upon the great trochanter are communicated to the pelvis, there is strong reason to believe that there is no fracture.

With respect to the shortening of the limb as a symptom of fracture of the neck of the thigh bone, though it is of great value, it is one which must be regarded with great suspicion, when found alone, because it is not an unfrequent occurrence in the absence of fracture. Old age seems to bring with it, as a tolerably constant circumstance, a change in the length and direction of the neck of the femur, but as a consequence of falls upon the trochanter it may occur at earlier periods of life. In these cases the distance between the summit of the trochanter and the crest of the ilium is always lessened. Five very interesting cases of this affection are described by Mr. Gulliver, in the 128th number of the *Edin. Med. and Surg. Journal*. The appearance presented by the femur is here shewn (fig. 6).

The point of the foot is almost always rotated outwards, so that the heel rests near the level of the internal malleolus of the other side; this rotation outwards is not always produced at the time of the accident, sometimes not for some days afterwards. Some persons attribute this to the action of the rotator muscles, others have attributed it to the tendency of the foot to incline outwards. Sir A. Cooper believes it to be the weight of the limb. Paré, Petit, and Desault, speak of cases where the toe was twisted. Desault says he frequently met with it. Morgagni, Martin, Dupuytren, Guthrie, Goyraud, Sanson, Syme, and Gulliver, refer to cases they had seen; other cases are on record, and attempts have not been wanting to shew that

Fig. 6.

this position is one of the principal symptoms of fractures of the neck, when this part has been driven into the great trochanter. Guthrie says, that whenever the fracture is external to the insertions of the pyriformis, gemelli, obturatores and quadratus muscles, yet sufficiently within the insertion of the glutæus medius and minimus, the toes will be turned inwards; and certainly Gulliver's case confirms this observation. Dupuytren thought the obliquity of the fracture had much to do with the position; if the line of fracture were backwards and outwards, he thought the point of the foot would be everted; if the direction were the opposite, there would be inversion. However, though inversion may happen, it is extremely rare; and I am astonished to find Desault state that the proportion in which the rotation is outwards, is only four to one. Boyer never saw the toe turned inwards. Cloquet has seen above 60 cases, but not a single case of inversion; once in an old woman he saw the foot directed straight; and so strongly was Delpech convinced that union was never obtained without shortening and eversion, that for many years he offered 2000 francs for any properly authenticated specimen of union without deformity.

If we compare the symptoms we have enumerated as marking fracture, with those of the different kinds of luxation of the femur, we should say that it was easy to distinguish diseases, that the ancients had confounded.

It is especially luxation upwards and outwards that has occasioned this mistake;

yet fracture of the neck of the femur has nothing else in common with it than shortening of the limb. The impossibility of restoring the limb to its proper length by moderate traction; the preservation of its length when once the head of the bone is replaced in the cavity from which it escaped; the impossibility of turning the foot outwards, should be sufficient to enable us to distinguish between these two injuries. In the luxation upwards and inwards, the head of the femur being directed upon the pelvis, the limb is shorter than the sound one, and the foot is everted; but it is impossible to bring the foot to its proper direction, or to give the limb the length it has lost, without reduction. It is still more difficult to mistake the signs of the other luxations. I am not, however, disposed to deny that there are cases where the displacement being null, it becomes very difficult to decide upon the existence of fracture. A man advanced in age fell upon the trochanter; the limb was shortened about half an inch; no other peculiarity was manifest. An eminent surgeon decided that there was fracture of the neck of the femur; a second surgeon confirmed the opinion; a third said the shortening might depend upon muscular retraction; but, as nothing indicated this retraction, the fracture apparatus was applied. The patient died of ascites on the fiftieth day. Upon examination, fracture of the neck was discovered.

In a few words, I will repeat the diagnostic signs which announce fracture of the neck of the femur; a fall on the trochanter, the knee or the foot, pain in the hip, inability to flex the thigh upon the pelvis, the leg being extended upon the thigh, the shortening of the limb, the possibility of restoring it to its proper length, which is again lost when we cease to extend it, the inclination of the knee and foot outwards, crepitation after making extension and rotation, and the small extent of the arcs of the circles which the great trochanter describes. If the absence of any essential symptoms should raise a doubt, the application of the fracture apparatus is no less necessary; it may be useless, but can rarely be dangerous, for a few days will generally remove all obscurity.

It is of the highest importance with respect to the prognosis, and even to the treatment, to determine whether the fracture is intra or extra-capsular. According to Sir A. Cooper, the greater number of the symptoms we have enumerated belong to the former; those of the latter are the following:—1st, the accident happens in young subjects; 2nd, it results from considerable external violence; 3rd, crepitation is more easily perceived; 4th, the trochanter major is directed forwards, and

is nearer the crest of the ilium, than in the natural state; 5th, the pain is greater; 6th, the limb is less shortened; 7th, rotation is more easily executed; but you will meet with cases where even with this assistance you will fail in determining whether the fracture be intra or extra-capsular.

However simple fracture of the neck of the femur may be, it is usually complicated with contusion of the soft parts around the joint.

The possibility of osseous union in cases of fracture of the neck of the femur, is a point in pathology which has been the subject of much controversy. It has been said that osseous union within the capsule could not take place; either because the osseous juice, contributing to form the callus, was dissolved in the synovia, because the upper fragment did not possess the necessary vitality, or because of the absence of the periosteum; but neither of these points are tenable. Besides, it is certain that fractures of the neck of the femur may be united by bone; the cases of Amesbury, Van Houte, Stanley, Brulatour, and many others, as well as the specimens existing in museums, are evidence of this—that this union may happen without riding of the bones or very sensible shortening of the limb; still in most cases the union is fibrous, and sometimes there is no union. When the fracture happens near the head, and the fibrous membrane is completely destroyed, it is said that the nutrition of the superior fragment languishes, that it is only supplied by means of the small vessels passing through the ligamentum teres, and that this is sufficient to enable it to contribute its proportion towards osseous union. Much of the difference of opinion which exists on this subject is owing to two circumstances: many persons have only observed the accident in old people: now in old people the vascularity of bone is reduced to its minimum, and therefore unfavourably disposed for union; and in the great majority of cases, the means of preserving immobility are insufficient: persons consequently believe that osseous union is impossible: those who have had opportunities of seeing the accident at different ages, (and certainly those opportunities are unfrequent; of 225 cases of intra-capsular fracture, Sir A. Cooper states that only two were under 50,) and who have employed machines capable of maintaining absolute rest, are satisfied that bony union may be obtained. Langstaff has a specimen taken from a man of 32. Stanley had a case of 18; he died three months after the accident, and the fragments were found to be united by bone. Many eminent men, and among them Sir A. Cooper, state that they have never known a fracture, fairly within the

capsule, united by osseous matter ; his French translators on the contrary think osseous union takes place in one case out of 50. The various specimens of osseous union seen in museums do not appear to them to be conclusive, because, as they allege, some portion of the fracture extended without the capsule.

It would appear, at first sight, surprising that a fact so easily determined should have so long remained undecided ; but, to some extent, this is accounted for, when we know that some who have taken part in this discussion have reasoned on incorrect data. A large number of anatomists have stated that the fibrous capsule is inserted into the femur in the course of the line descending from the greater to the lesser trochanter. They have, it is true, mentioned a reflexion of the capsule setting out from the base of the neck to pass towards the head, but no one has mentioned the exact limit of the femoral circumference of this capsule. Now what is this limit? In the anterior and superior part the capsule is attached to the parts already mentioned, but inferiorly and posteriorly, the capsule is inserted along the neck to the union of the external with the middle third. It must, therefore, follow that all fractures seated in the inner half of the neck of the femur must be intra-capsular; then, it is said, the internal fragment is so badly supplied with vessels, that consolidation is hardly possible. It is further believed that, when a fracture is some distance from the base of the neck, but in its outer half, it may be perfectly united, because the fragment attached to the head is connected with the capsule, and receives from it enough of vessels to enable it to take its fair part in the work of osseous consolidation. Thus it is believed that contradictory opinions may be conciliated. Certainly, if these data be accepted as correct, the cases which I have seen of undoubted bony union go so far in confirmation of Sir A. Cooper's opinion, that they were all on the outer half of the neck, and, consequently, extra-capsular. The causes ordinarily assigned for non-union by bone in these cases are, want of necessary nutrition in the superior fragment, difficulty of maintaining contact, which I hold to be out of all comparison the most decided cause of failure, and, according to Sir A. Cooper, the absence of pressure of one fragment against another.

I have no doubt but that age is the main cause of this discrepancy. Ruysch mentions many cases transmitted to him by Gerard Borst, who was attached to an asylum for old women at Amsterdam. In all those cases he believed great age constituted an invincible obstacle to the formation of callus, the head of the bone

becoming shrivelled and ligamentous ; but this is not the cause, because in very advanced age union is obtained in other situations. It is impossible to determine at what period, in such cases, we should cease to expect a cure. Lesne used to exhibit the femur of a woman of 89 which had been united by bone. Many similar facts seem to me to lead to the conclusion that proper attempts to cure should be made. I have thought it quite necessary to say thus much on the subject, because if intra-capsular fracture could not unite by bone, and if ligamentous union is, as some persons say, as advantageous, if not more so, why subject the patient to a permanent, painful, dangerous, and always inefficacious extension? why keep the patient in bed many weeks.

CLINICAL LECTURES,

Delivered at St. Vincent's Hospital,

By J. M. FERRALL, ESQ., M.R.I.A.

First Medical Adviser to the Hospital.

Gastritis, subacute, a frequent complication of other diseases—Cases of subacute gastritis treated by depletion and diet—Kreosote in obstinate vomiting—Two forms of organic disease of the pylorus, generally distinguishable during life—Stricture of the pylorus without cancer—Cancer of the pylorus without stricture—Diagnosis.

GENTLEMEN,—In the selection of cases for your instruction, I have thought it expedient to bring under your notice what is useful, rather than what is rare, in practice; convinced, as I am, that many pupils quit their studies with their note-books filled with medical rarities, while they are ill prepared by observation for the ordinary duties of their profession. I shall, therefore, occasionally mingle such inquiries with the more serious objects of our researches.

There is an affection of such common occurrence that you can have no pretensions to the rank of a well-informed practitioner without being perfectly familiar with its symptoms and treatment. You may term it subacute gastritis, gastric irritation, or acute dyspepsia, in accordance with different authors; but it is little matter by which denomination you express it, provided you are prepared to recognize its approach, and are competent to its management. It may arise in the course of some surgical disease, or subsequent to an injury. It may complicate a fever, of whatever origin, or (it is in vain to deny it) it may spring up in consequence of the treatment employed to subdue a pneumo-

nia, or some other acute disease. Under any of those circumstances, to overlook gastric disturbance of an urgent character would be to compromise the safety of your patient. You cannot, therefore, bestow too much pains on the study of this important subject.

Three cases of gastric irritation, or subacute gastritis, have been discharged this week, and two post-mortem inspections have been made in cases which were admitted in a hopeless state of organic disease of the stomach. The two latter are instructive specimens of the two varieties of organic lesions of this organ, to which I have before called your attention. You witnessed the difference in their symptoms; you have now the parts before you, and can see whether my explanation of the cause of this difference is founded in reality. I have long been convinced that many cases were termed cancer of the stomach which really had not the essential characters of that malignant disease; and I believe that, in many instances, the phenomena displayed during life were sufficiently distinctive of those affections. The two cases to which I allude have been now under your observation for some time, and you are consequently prepared to follow me in their analysis.

We shall first briefly dispose of the cases of gastric irritation.

Vomiting—Epigastric tenderness—Loss of flesh—Cure by depletion and low diet.

Eliza Higginson, æt. 20, was admitted December 5th, complaining of severe pain at the pit of the stomach, loss of appetite, chilliness, and occasional burning heat. She frequently vomits her food, which returns with a remarkably sour flavour. She is thirsty. Her flesh and strength are greatly reduced; skin hot; pulse 90; tongue slightly coated in the centre, with florid tip and edges. The bowels are confined; urine scanty, and high coloured, and acid. Epigastrium tender and tumid. She is impressed with the notion that her complaint is all weakness, and has taken ale and porter every day, although she now admits she suffered more in consequence. The catamenia is regular. She has never been well since she met with an accident by coming in contact with the shaft of a car, about two months ago, but had no other ill consequence.

Cupping on the epigastrium to eight ounces. Arrow-root in small quantities. The bowels to be freed by enemata, and the following powder to be taken three times daily:—

R Sodæ Bicarbon. ʒj.; Sacch. Alb. gr. v. M. pulv.

December 10th. — She has not had

vomiting since her admission. Urine paler, and more copious, but still acid; bowels free; tongue improved in colour.

Pergat.

20th.—Feeling herself quite well, she requested a little meat a few days ago, but suffered pain that night; on which account a small blister was applied to the epigastrium. There has been no pain since. The vomiting never occurred since she came into the hospital. Her strength is improving, although her diet is exclusively farinaceous. The skin is dry, but no feverish heat is felt now. Pulse 72. A warm bath is ordered.

24th.—Feels quite well. Discharged.

Constant vomiting—Epigastric tenderness—Depletion—Kreosote.

Mary Bardin, ætat. 25, was admitted on account of constant and painful retching, great soreness and pain at the pit of the stomach, and excessive exhaustion. She had been an out-patient for bronchitis. The liquor antimon. tartar, in half-dram doses, had succeeded in removing the pectoral affection, but the stomach became disordered. She discontinued her attendance at this time, believing that the stomach would improve when she took more liberal diet. This only aggravated the evil; and, after ten days of suffering from vomiting, which gradually increased until even cold water was rejected, she begged to be admitted into the hospital.

The epigastrium was tender; the tongue coated; and, at the tip, studded with red points. Pulse feeble and small. Skin hot and dry. Countenance haggard, and expressive of pain. Bowels easily moved, and without pain. Urine scanty.

A sinapism was laid on the epigastrium, and she was directed to take a scruple of aqua lauro-ceras three times a-day.

The next day the report states that the vomiting is less frequent, but continues still; there is more reaction, and the pulse is more voluminous. She was then cupped on the epigastrium to six ounces, which removed the pain and tenderness altogether. Cold water in sips remained on her stomach, but every thing else was rejected. A drop of kreosote, with mucilage and water, was administered every fourth hour with the best effects; the retching ceased, and arrow-root and boiled bread-and-milk were retained. From this time she improved rapidly. The renal secretion increased under simple treatment, as effervescing mixture, and she was dismissed free from complaint on the eleventh day from her admission.

Chronic gastritis—Epigastric tenderness—Depletion—Cure.

Anne Dunne, ætat. 38, had repeatedly suffered from pain in her stomach, with

vomiting of sour fluid. On more than one occasion she has attended as an out-patient, and received complete relief from antacids, mild aperients, and counter-irritation of different kinds. Within the last three months she has been losing flesh, and has suffered so much after meat or stimulating diet, that she has given them up altogether. Her countenance is not sallow, though her face is thin. Her tongue is rather clean, but too red at the edge. Pulse 80. Bowels confined. Urine in natural quantity, but depositing deep-coloured lithates. She suffers greatly from flatulence; and has been induced to take stimulants, as pepper-mint, on account of the immediate relief which follows their use. She has constant thirst, and desire for cold drinks. Catamenia regular. No pectoral disease.

This patient had learned by experience to manage her own diet; and the only error she committed was in the use of stimulants, and in postponing her application for proper aid. She was ordered to remain in bed, was cupped on the epigastrium, and had equal parts of aqua calcis and warm new milk three times a-day. The bowels freed by enemata.

Four days afterwards the report states that the flatulence is very much diminished, and she bears pressure better on the epigastrium. No tumor or circumscribed hardness was to be discovered in that region. The bowels were acted on by emollient enemata, which she found to diffuse a sensation of comfort through the abdomen and stomach.

As the case had now become chronic, and as frequent attacks had succeeded each other for a period of two years, it was deemed advisable to establish a permanent counter-irritation over the epigastric region. For this purpose two moxæ were applied. The pain of this application being of very short duration, is better borne than that from caustics of other kinds.

In a fortnight this poor woman was so far recovered as to desire to return home. The issue was established over the former seat of pain. Soda was occasionally given in lieu of the aqua calcis, but was always discontinued when the urine showed a neutral or alkaline reaction. Her tongue became pale and moist. She lost the thirst, and was now able to take a little chicken with impunity.

In the latter case, considering the period of life, the frequent recurrence of attacks, and the loss of flesh, there is reason to apprehend that if she relaxes in her attention to diet, or neglects the earliest intimations of irritation, organic disease of the stomach will ensue. We frequently see persons go on for years, occasionally suffering from gastric irritation, and at other

times quite free from complaint; until, at length, the attacks settle into disease of an incurable nature. An instance of this kind will occupy us presently, in the case of poor O'Shanghnessy, who died a day or two ago.

The first case, Higginson, showed the advantage of decided treatment, and of depletion whenever the epigastrium is tender permanently. By this I mean, when the tenderness is not the sequela of an attack of gastrodynia, or spasm, or the soreness which remains after violent vomiting, and which latter often resides in the abdominal muscles. You should not omit depletion by cupping or leeches whenever there is evidence of hyperæmia of the organ, suggested by the florid tongue, thirst, hot skin, local heat over the stomach, and deep-seated tenderness on pressure. This being premised, your other remedies will produce a better effect. The state of the renal secretion will often assist your diagnosis, although you must not forget that copious fluid vomiting will render this secretion scanty.

The second case, Bardin, evinces the efficacy of kresote in obstinate vomiting. The advantages of this remedy were first insisted on by Dr. Elliotson, and have since been acknowledged by Dr. Burne, of the Westminster Hospital, who has employed it in irritation both of the stomach and bowels with success.

Of the two forms of organic disease of the pylorus to which I alluded, and which are preceded or accompanied by symptoms of chronic gastritis, one consists in hypertrophy of the tissues entering into this portion of the organ, and appears to destroy the sufferers by increasing constriction of the orifice, impeding the passage of the aliment, and literally starving them to death. The other presents the characters of an essentially malignant change—involves other organs generally—and frequently ends in the dissolution of the patient, without any mechanical obstruction in the part.

Stricture of the pylorus without cancer—Death from inanition.

Mary Cousins, æt. 39, stated on admission that she had been labouring for six months under her present complaints. They commenced by a sudden attack of vomiting without any evident cause. She had pain in the stomach, but does not describe it as having been severe. This acute attack gradually subsided without treatment, but left a disinclination for food, and pain after eating. The vomiting, which during the acute invasion brought up every thing, solid and fluid, immediately it was swallowed, was then much less frequent, and only followed the ingestion of animal or stimula-

ting food, and she began to think herself well. But latterly, milder food returns, and she suffers pain after every meal. She is remarkably emaciated, and describes the change in this respect as being very great within the last month; her features are drawn and lengthened; the nose is blue, as if from cold; the lips pale; tongue slightly coated, with red edges; pulse small, 100; skin dry; bowels obstinately constipated: she says three weeks elapse between the evacuations. On examination, a hard tumor, about the size of a small apple, is found to the right of the umbilicus; there is tympanitic distension, especially of the left side of the abdomen; very little pain on pressure.

This was the report of her state on admission. Several days elapsed before the bowels yielded to enemata, and then a very large faeculent discharge took place; a dose of aqua lauro-ceras, before her slight meal of arrow-root, seemed to cause it to be retained, but we found on inquiry that the vomiting was only postponed. She did not vomit after every meal as heretofore, but it gave her pain; and now an attack of vomiting was observed to occur regularly at 5 o'clock every morning. On inspection, the quantity ejected was found to exceed greatly what had been ingested; it consisted of a brown fluid, like chocolate, mixed with mucus and some traces of the food; the bowels remained confined, and acted not more than once a week; the urine brown and scanty; the tongue generally dry. The saliva sometimes yielded an acid reaction, but nothing satisfactory could be said on this point, from the variable nature of the results. She suffered from thirst, but dreaded swallowing on account of a peculiar distress which followed it: together with the pain, a remarkable sensation of regurgitation immediately commenced (and could be felt by the hand laid on the abdomen,) at the seat of the hard tumor; from this point it ascended towards the cardiac orifice, and thence returned again. Nothing could exceed the dread she felt of exciting this painful state.

I need not remind you of the various remedies employed to soothe her sufferings. Preparations of hydrocyanic acid, bismuth, kreosote with opium, belladonna externally and internally, &c. &c.; all of these produced relief for a time, but I think she derived more frequent comfort from kino and acetate of morphia. This copious secretion of mucus, as well as the flatulent distension of the stomach, appeared to be in some measure diminished by this plan. The chocolate-coloured vomiting, however, persisted, and was only occasionally controlled by the exhibition of the tincture of the muriate of iron.

With a view to sustain this poor woman,

enemata containing strong broths, milk, and arrow-root, were tried, and seemed for a while to revive her; at length she began to sink more decidedly, her voice became husky and reduced to a whisper; her pulse scarcely palpable; her tongue icy cold; the surface generally, cold and bluish, and reminding us of the collapse of cholera; the evacuations by the bowels more rare; occasional hiccup. She lay for several days in a torpid state, sleeping with the lids half closed, and scarcely living. The vomiting occurred regularly until she was released from her sufferings.

Autopsy.—Remarkable congestion in the veins of all the intestines as well as of the stomach. The vessels large, and marked by a brownish dark blood. The stomach was enormously distended, and taking an unusual course. The whole left half of the abdomen was occupied by this organ, which descended directly into the left iliac fossa; thence it ascended towards the umbilicus, to the right of which was situated the hard tumor of the pylorus, which had been felt during life. The stomach contained a large quantity of brown fluid similar to what has been ejected; the mucous coat was tinged of the same colour; the veins large and congested. The thickness of the stomach in its pyloric third was such as to make it resemble leather to the touch. A section of this portion, you perceive, reminds us of a thickened urinary bladder with deceased prostate gland; the passage into the duodenum would hardly allow the passage of a probe: the contracted portion was near three-quarters of an inch long, and ascended by a curve to the duodenum.

On examining the section carefully, you perceive the tunics are all thickened, but there is no breach of surface. The mucous coat presents no trace even of abrasion. The brown chocolate fluid was then an exhalation from the surface of the membrane. You cannot dissect off the mucous membrane without the sub-mucous cellular coat. They come off together, and appear to be connected with the muscular coat by a fine cellular tissue. This is not exactly what Andral describes; for he mentions the thickened cellular tunic dipping by bands between the muscular fibres, and connecting itself with the sub-serous cellular tissue. The muscular coat, when washed, presents very much the colour and appearance of the muscle of a fish; the fibres are distinct, but hypertrophied. The thickness of the section is rather more than half an inch at the pylorus, and rather less than half an inch below that point.

The liver was dark coloured, but contained no morbid deposit. The gall bladder was very large, and filled with deep-yellow coloured bile; the spleen of

moderate size; the kidneys rather small, and of a venous colour on section, but presented no other change; pancreas healthy.

We shall now pass to the case of O'Shaughnessy, and conclude by contrasting it with the former.

Cancer of the pylorus without stricture.

Ellen O'Shaughnessy, æt. 40, was a patient in St. Vincent's Hospital on a former occasion, (twelve months ago). She suffered, at that time, from pain after food, tenderness below the ensiform cartilage, distressing burning sensation, and acidity. This state succeeded to a rather sudden attack of pain and vomiting, which she attributed to interruption of the menses. She never ventured to use animal food afterwards without suffering immediate pain and burning heat, and, within half an hour, rejecting the entire. She applied to a medical gentleman for advice in the beginning, but states that no depletion was employed. On her admission for the first time into the hospital, she had leeches applied, and blisters, and took small doses of opium, with antacids, with good effect. Her appearance improved, though not very much, and she returned home, feeling quite well, but exhibiting a sallowness of complexion which did not belong to health; farinaceous diet was advised.

She then went to attend a lady, who pressed her to use a more nourishing diet. In deference to this advice she tried wild fowl in small quantity, but soon wished to give it up, on account of returning pain. Her patroness insisted on her persevering, and assured her of success, alleging that she only wanted proper nourishment to restore her completely. The pain, however, increased; she became feverish again, lost colour and flesh rapidly, and, although the vomiting seldom occurred now, her suffering was so great, after even the mildest food, that she lost rest altogether.

In this state, after an absence of twelve months, she begged to be re-admitted into hospital. She was now so altered in appearance, that she was not recognized at first. Her voice was feeble; her colour sallow. She was emaciated, and her countenance wore the aspect of malignant disease.

The abdomen, on examination, afforded abundant evidence of organic disease; a large tumor occupied the epigastric region, and could be traced upwards under cover of the ensiform cartilage and ribs. The whole of this region was dull on percussion, as well as the right hypochondrium; a distinct bulging prominence marked the centre of this solid mass. The abdomen was rather shrunken, and had little of a

tympantic sound. The pain she complained of extended, she said, through the bowels towards the pubic region. She had occasional diarrhœa and griping, but not constipation at any time. It was evident that extensive organic disease existed in the abdomen; the bulging prominence was considered to be a tubercle of the liver: the situation of the pylorus could not be ascertained.

The principal indications, namely, to moderate the diarrhœa, and lessen the sensibility of the mucous surfaces, were attempted by cretaceous preparations, with opiates, aqua calcis, rice, flour and milk, &c., with varying success. Every remedy seemed of use at first, but soon ceased to exert any control over the symptoms. The same remedy was often resorted to again with advantage, although it had, before, ceased to procure relief. The diarrhœa was remarked to produce very fetid discharges. The renal secretion was generally scanty, and remarkably loaded with purpurations; her colour now became more jaundiced; she had occasional perspirations at night, and lost strength rapidly; she had hiccup. The pain was absent occasionally for several days together, and certainly became much less distressing. For two or three weeks before her death she had no vomiting; but the diarrhœa became less manageable even by opiate enemata. The dejections became paler, but still very fetid. The tongue dry and brown; the pulse faltering; the hiccup more frequent. She sank in a semi-comatose state. The saliva was occasionally acid during this period.

Autopsy.—*Head.*—The vessels of the brain (the veins and sinuses) were rather turgid; no remarkable arterial vascularity. The consistence of the brain was rather firm; no sub-arachnoid or other effusion.

Chest.—The pleuræ costalis and pulmonalis were adherent at several points of right chest; a few tubercles were found in a crude state in the apex of that lung. No disease in the left side. The heart was rather small; muscular substance softer than natural; cavities and orifices normal.

Abdomen.—The peritoneum was adherent in a few places, and connected the liver to the diaphragm. The liver was large, and presented a striking example of the soft tubercle. You observe the masses are circumscribed accurately, have a yellow colour, are depressed in the centre, and are marked by numerous radii formed of blood-vessels proceeding from the liver towards the centre of the morbid growth. Their circumscription, in the substance of the liver, is complete; for you perceive they can be turned out entire, and without destroying any thing but a very fine cellular

tissue which surrounds them as they lie imbedded in the organ; a section exhibits a yellow soft encephaloid substance, almost creamy in some parts, enclosed by septa of a firmer consistence and a whiter hue. There is no very apparent arrangement of the septa. Some of the tubera are excavated in the centre, or softened into a puriform fluid. The stomach was rather contracted; it lay concealed by the liver, and by a mass of morbid growth which surrounded the pylorus, and extended behind it towards the spine. Several globular tubera, as large as filberts, were found in this mass: their structure was similar to those in the liver. The gall-bladder was small, and contained a little dark green bile. On opening the stomach, a large sloughy excavation occupied the place of the pylorus; the surface was irregular; in some places reduced to a pulp; and in others, where sloughing had not occurred, gristly to the feel. This large ulcerous cavity was smeared with a peculiarly fœtid sanies. The passage of the pylorus was open and large, and admitted two fingers to pass readily into the duodenum. A section of this mass shewed a surface of cartilaginous appearance, striated, but exhibiting no trace of the tunics of the organ. The stomach exhibited little thickening beyond the seat of this cancerous disease. The mucous coat of the intestines was tumid and vascular, towards the termination of the ileum; no abrasion was discovered. The spleen and kidneys presented nothing remarkable.

You will now, gentlemen, understand why I desired your special attention to the phenomena which, so very different from each other, characterized those cases during life. You will also be convinced of the value of minute anatomical analysis, post-mortem, by the clear and satisfactory explanation which, in these two cases, it affords of the symptoms you observed.

In the case of Cousins, the pylorus, though less extensively diseased, could be felt during life, because, in the first place, no other tumors existed to conceal it; and secondly, because the enormous distension of the stomach, occasioned by the permanent obstruction at its orifice, brought it lower down into the abdomen. But how are you to recognise a pyloric tumor, so far displaced inferiorly, as to be on a plane with the umbilicus, and laterally, as to be placed in the right side of the middle line? Might it not be a tumor of the omentum, or other growth connected with the intestines? If you adopt this rule, you will seldom be deceived. Percuss the proper region of the stomach, and discover its peculiar tympanitic clear sound. Then follow this sound, by progressive percussion downwards, till you lose it, and finally

pass to the right, till your fingers are conducted by this sound to the spot occupied by the pyloric tumor.

It is to Andral we are indebted for precise notions of hypertrophy of the tunics of hollow organs, as distinguished from other changes of a more malignant nature. He remarks the enormous distension of the stomach, which occurs in pyloric obstruction from this cause, and records examples where the contents were rejected only every seven or eight days. He also notices the fact, that chocolate or coffee-coloured fluids may be vomited in cases which present no abrasion of the mucous surface. The case of Cousins is well calculated to support his opinion, and shows that this kind of vomiting is not, as it was considered in Dr. Baillie's time, pathognomonic of cancer of the stomach. Dr. Baillie does not appear to have recognised this disease. He describes stricture of the pylorus as caused by a "permanent contraction of its muscular fibres," and accounts for its occurrence at the pylorus, more frequently than at the cardia, by the "fibres at the pyloric end being more circular in their direction," and possessing "a stronger contractile power." He adds, "I have seen one instance of this contraction at the pylorus, which, even there, is a very rare disease." It is difficult to say whether this is meant to apply to a case of hypertrophy, or whether he may not have been deceived by the contracted state of the pylorus, which often exists at the moment of death; but which did not exist, perhaps, an hour before that period, and which is easily removed after death, by the slightest dilatation, without injury to the parts. I believe this to be possible, because I have more than once seen a contracted state of this orifice exhibited as a disease, when the largest finger could be readily passed through it, and when the tunics, thus separated, were perfectly natural in thickness, pliability, and consistence. In the section entitled, "diseases of the pylorus," that distinguished pathologist, Dr. Abercrombie, describes some of the prominent symptoms; but does not contemplate any distinction between the cases in which hypertrophy without cancer is to be found, and those in which the essential characters are malignant. Indeed he does not appear to have examined the parts with that minuteness which alone could have enabled him to make the distinction. He gives three cases, and in the first states merely that "the pylorus was surrounded by a mass of schirrus, the size of an orange, very firm, or nearly cartilaginous;" "the stomach in other respects was entirely healthy." In the next case, he says, "a mass of schirrus, four or five inches in diameter, surrounded the pylorus,

and the pyloric orifice was so narrowed as scarcely to admit the point of a very small finger. The inner part of the mass opened upon the internal surface of the stomach by an ulcerated space, covered with large cancerous-looking tubercles. The other parts of the stomach were tolerably sound." In the third case also, he describes the external tumor and the internal surface, or that presenting into the cavity of the stomach; but the structure of the mass is not displayed by a section, by which, and a short maceration, the true nature of the tumor can alone be determined.

Returning then to the two cases before you, you will observe that they differ from each other in anatomical characters, in localization, in their progressive changes, in the cause of death, and in certain symptoms manifested during life.

In the first case (Cousins) there is hypertrophy of the tissues, but they are distinguishable: it is as if they were placed under a lens and enlarged. In the second case, the tissues are disorganised, and confounded together.

In the first case, the disease is local, and seems to arise from gastritis of long duration. In the second case, the taint is general, and other organs are involved in the malignant change.

In the first case, the disease ran its course to a fatal issue, without any breach of the mucous surface. In the second case, ulceration was probably an early change, for the opening was considerably enlarged.

In the first case, the patient died from irritation, the pyloric orifice being almost completely closed. In the second, the passage was larger than natural, and the patient sank under the disease of several organs, and the general taint.

In the first case, the patient had a peculiar, cold, pinched, and starved look; the vomiting continued up to the time of death, and the whole ingesta were returned; and there was constipation, or, I should prefer calling it, rarity of faecal discharges, for constipation means a different state. In the second case, the aspect of the patient was that of malignant disease; the vomiting became less frequent, and ceased before death; and there was an opposite condition of the bowels, or diarrhoea*.

I may remark that, in cases like the

first, the vomiting of each meal separately may be generally prevented by suitable remedies; but you must not be deceived by this event; for the food will no less certainly return, as soon as the stomach becomes so much distended as to bear no further accumulation; and this I have remarked to occur more especially in the horizontal posture.

The state of the gall-bladder is worth a word or two of notice. It was found in the first case greatly enlarged and distended with bile. Now, this appears to be connected with absence of chyme in the duodenum, and the want of the accustomed stimulants to the biliary ducts. Morgagni relates the experiment performed by Val-salva on a dog which he, cruelly enough, starved to death. The gall-bladder was unusually large, and distended with bile. The starvation in poor Cousins's case was the result of organic obstruction. The celebrated surgeon, Mr. Carmichael, suggests as an explanation of the occurrence of gall-stone in the human subject, the pernicious habit of long fasting and late dinners, which so generally prevails. I have no doubt that, in many instances, gall-stones have their origin in this way; but some other cause must occasionally coincide to produce the result. In Cousins's case, for instance, there was long and painful fasting, and the gall-bladder was found distended with bile, but there was no gall stone in that case.

REPORTS OF CASES.

By H. M. HUGHES, M.D.

Physician to the Surrey Dispensary.

Scarlatina.—In the eight cases of this complaint, of which I have preserved some records, nothing, with the exception of the circumstances attending the fatal case, is worthy of notice. The disease, in these and all other cases I have seen during the year, was mild, and the affection of the throat trifling. Suppuration occurred in none, and very slight anasarca without coagulable urine in only two or three. The treatment was of course very simple, and, as regards medicine, merely nominal. The bowels were kept moderately relaxed by saline aperients: when the rash was vivid, and the heat intense and distressing, tepid sponging was employed to the great comfort of the patients: if, on the contrary, the rash appeared but faintly, a little ammonia was given in a diaphoretic mixture: an ammonia lini-

* Subsequent to the delivery of this lecture, a series of preparations and drawings, and cases illustrative of these two pathological states, were laid before the Pathological Society of Dublin, (See Dub. Journal,) and later still I have had the satisfaction to observe that Dr. Addison, the distinguished Physician of Guy's Hospital, has arrived at similar results, in arranging the two classes of disease.

ment was applied to the throat, if the fauces were inflamed. The patients were generally kept cool as long as the rash continued, and warm, with flannel next the skin (when it could be obtained), with a view to prevent succeeding anasarca, for two or three weeks after the exanthem had disappeared. In consequence of the employment of these means, I believe it was that very few cases were followed by anasarca. I have already said that a great number of cases in the district were so mild as not to require medical assistance, and as, in some instances, not even to have attracted the notice of the parents of the children affected. In such it was only after application for advice for some succeeding complaint, that, upon investigation, it appeared evident that the children had suffered from scarlatina. Death, in the fatal case, arose from inflammation of the brain. A marked illustration was afforded by it of the fact, that accidental complaints, affecting the system generally, fall with the greatest violence upon organs which have been previously injured by disease, or, in other words, that the weakest parts suffer most. The case is very briefly as follows:—H. L., aged three, a child with dark hair and eyes, who, two or three weeks before, had recovered from a severe and dangerous attack of meningitis, contracted scarlatina from her brother and sister, who passed through the complaint very favourably. Nothing remarkable accompanied the premonitory symptoms, excepting an increase of her natural excessive peevishness and irritability. The rash appeared faintly on the face and trunk on the second day. On visiting her the next morning, I found the skin pale, the eyes heavy, the head hot and painful; that she was exceedingly restless, complained of the light, and frequently screamed; the tongue was thickly coated, and the pulse frequent, small, and sharp. She was ordered a hot bath, leeches to the temples, a cold lotion to the head, an active purgative, and small repeated doses of calomel and antimony. My directions were but indifferently attended to, and my efforts feebly seconded: the rash did not reappear; no relief was obtained; the child became partially comatose, and died on the sixth day of the disease, and the third after the retrocession of the rash. Permission was not obtained to inspect the body.

Sequelæ of Scarlatina.—The only affection I shall notice under this head, and, indeed, the only one of importance I have been called upon to treat during the past year, is anasarca. This, in the district to which these observations apply, and, I believe, in the metropolis generally, has been exceedingly common. The children labouring under the complaint have, in a great majority of instances, been brought to the dispensary: with the exception of the case of an adult, who, from his former habits, combined with the state in which the kidneys were found after death, I believe must have suffered from disease of those organs before the attack of scarlatina, and whose case has, therefore, been introduced among those of renal dropsy, the whole have terminated favourably. It is, I think, the custom of medical men to regard this affection too lightly. It is true it is usually amenable to a great variety of treatment: thus the cases of one practitioner are said to do well under the tonic; those of another, under the diuretic plan of treatment; a third gives these remedies combined; and a fourth trusts to purgatives. Gentian is infallible with one; digitalis, or a combination of the two, is regarded almost as a specific by another; nitric acid, digitalis, and calomel, are especially advocated by some; and “they all get well with purgatives,” is confidently stated by others. It appears evident, I think, from this variety of treatment, that no very definite notion is entertained, by the profession at large, of the pathology of this affection; and, as cases occasionally occur which terminate fatally, and probably more frequently in which the germs of important disease in the kidneys are then for the first time introduced, I may, perhaps, be excused for directing a few observations to the subject.

In 1818, a paper appeared in the Edinburgh Medical and Surgical Journal, from the pen of Dr. Abercrombie, in which the author stated his belief that acute dropsy, cured by bleeding, and accompanied by coagulable urine, was dependent upon inflammation of the lungs: the opinion was supported by dissections. In the same paper were introduced cases of anasarca, following scarlatina, which were supposed to arise from the same cause. Dr. Bright's great discovery had not then been made, or had not been made public. It is possible,

therefore, that since that time Dr. Abercrombie's views upon this subject may have undergone some change or modification. I must, however, with all deference, express my dissent from the opinions then entertained by this celebrated physician. That the anasarca following scarlatina, and indeed that the acute dropsy generally accompanied with coagulable urine, and which is removed by venesection, is not dependent upon inflammation of the lungs, is, I think, sufficiently proved by the facts, that, in many examples of these forms of anasarca, there is no important disease, and in some no affection whatever, of the respiratory organs; and that cases of pneumonia equally severe, and equally sudden with those accompanied with this affection, are constantly occurring without any traces whatever of anasarca. A remarkable case, in proof of this, will appear in the course of these reports, under the head of pneumonia. That inflammation of the lungs often accompanies these cases of anasarca is undoubted; but it frequently first appears in the progress of the complaint, and, in many instances, only in the last stages of the fatal cases.

That the anasarca following scarlatina, as well as that of an acute kind, removed by venesection, is principally connected with, if not essentially dependent upon the suppressed secretion of the skin—in the one case, long continued, in the other sudden, and occurring while perspiration exists upon the surface—has long been my opinion. I shall, however, confine my observations almost entirely to that succeeding scarlatina. The sequence of the pathological conditions in this complaint, I believe, after some consideration, to be briefly and simply as follows. After the rash of scarlatina has disappeared, it is well known that the skin usually remains, for several weeks, in a harsh, rough, dry, unperspirable state, which is sometimes conjoined with frequent and long continued exfoliations of the cuticle. The natural cutaneous secretion is, in a great degree, or almost entirely, suspended. An increased quantity of fluid is probably, in consequence, exhaled from the lungs. This compensatory action, however, of the pulmonary mucous membrane, is only partial; and some portion of the fluid, which, in the healthy state, is separated from the blood by the vessels of the cutis, and

passes off as sensible or insensible perspiration, slowly accumulates in the cellular membrane beneath it. At the same time, or perhaps generally at a period prior to this event, the other excreting organs of the body become overcharged, a larger supply of blood is sent to the kidneys, and a state of active congestion of these organs results. The vessels of the secreting portion of the organ become dilated, and allow of the escape of the albumen or red particles of the blood, which almost constantly exist in the urine of these cases, but are usually not found in dropsy unconnected with any affection of the kidney.

After a time, the effused fluid being removed by purgatives, the skin resumes its healthy functions, and the kidneys generally a few days or weeks afterwards secrete urine of a natural character; but it appears probable that a dilated state of the vessels, or a passive congestion of these organs, may be sometimes left behind; and the probability is supported by the bloody or albuminous condition of the urine which often remains after every other appearance of disease has ceased. This state of the kidneys usually disappears almost spontaneously in healthy subjects; but in persons predisposed, and in others in whom the disease is neglected, it may go on, I feel assured, to organic changes of structure, and may be the cause of incurable and unmanageable complaints.

The view of the pathology of the complaint above detailed is sufficiently simple, and to myself appears, independently of confirmatory facts, to be exceedingly probable. The only objection that I have heard urged against it, of any weight, is the circumstance of the anasarca and coagulable urine not usually appearing until the seventh or tenth* day after the rash has ceased. It is asked, if the suppression of the cutaneous secretion is the cause of the anasarca, why does it not come on immediately? why, as in some cases of acute dropsy, is it not produced in a day? This is indeed a difficulty; but, I conceive, not an insuperable one.

Cases of acute dropsy, I believe, ge-

* I have assumed that the coagulability of the urine does not appear till some days after the cessation of the rash, as I believe it is by no means common to have coagulable urine, as stated by some authors, during the progress of either scarlatina or measles. I have examined the urine, while the rash existed, on several occasions, and never found it to coagulate, at least in children.

nerally occur from the sudden exposure to cold, while the body is heated, or the surface covered with perspiration. The vessels of the cutis are thereby suddenly contracted; the skin is hot, but it is pale; hot, because the cooling effect of perspiration and evaporation is not in operation; and pale, because the red vessels are reduced in number and in size. The consequence of this sudden suspension of the action of the cutaneous vessels is an almost equally sudden effusion below the cutis, and simultaneous congestion of the kidney. During scarlatina, on the contrary, a much larger than the ordinary quantity of blood is sent to and returned from the cutis itself; and it is probable that the cellular tissue below, far from being in a congested state, is even less turgid than in the natural and healthy condition. After the rash has disappeared, though the circulation in the cutis is certainly not *natural*, it is not, I think, really deficient; and, though its *healthy* secretion is not eliminated from its vessels, some secretion takes place, as is evidenced by the abundant and repeated separations of cuticle. It would then, I think, appear, *à priori*, not improbable, that in the one case the sudden suppression of the action of the skin might cause a sudden effusion below the surface, and an equally sudden congested state of the kidneys, and in the other, though the skin remain dry and harsh, and its action be changed in character, and deficient, but not materially decreased in amount, that the morbid effects might be less active in their kind, and more tardy in their appearance. That this form of anasarca is chiefly connected with decreased or disordered function of the skin is, I think, confirmed by the following considerations:—To no eruptive complaint does anasarca so commonly succeed as to scarlatina, and in none does the unperspirable state of the skin exist to so great a degree, and remain for so long a time. Where anasarca exists the skin is always harsh and dry, and when the functions of the skin begin to be properly performed the anasarca ceases. The anasarca is very quickly and advantageously removed, by the administration of such medicines, and the use of such means, as alter and increase the secretion of the skin. The anasarca appears to be in many, and probably might be in most cases, prevented by the use of vapour or warm

baths, flannel next the skin, diaphoretic medicines, and the adoption of such other measures as have a tendency to restore the healthy action of the surface. It is to the milder forms of the complaint that anasarca usually succeeds, where the action of the skin remains dry and torpid for several weeks; while in those examples of the complaint in which the rash is very vivid, the skin intensely hot, the subsequent separation of the cuticle abundant and quickly completed—where, in fact, the skin speedily resumes its healthy action and natural secretion—no anasarca (at least, according to my observation) is found to succeed. It does not materially affect the force of these confirmatory facts to acknowledge that the complaint is frequently removed by other means than those referred to; as, in a great majority of cases, the skin spontaneously resumes its healthy functions after the expiration of two or three weeks; and as the remedies employed only remove the effused fluid, the simple result, the mere effect of some pathologic condition, which, whatever that condition may be, is to be regarded as the real disease.

This anasarca, as I have before hinted, usually appears after the less severe forms of the complaint. In not a few, indeed, the dropsical affection, together with the previous history, as the existence, a week or two before, of sore throat, some febrile affection, and the prevalence of scarlatina in the immediate vicinity, has been the sole cause for believing that the patient had passed through the disease. In some even this sort of evidence has been wanting; but if scarlatina prevailed at the time, knowing the occasionally extremely mild character of the complaint, I have usually concluded that the rash, and the attendant fever, had passed without notice. In this I may sometimes have been mistaken, as children as well as adults are, I suppose, liable to idiopathic acute dropsy. I think I have also observed, that where considerable enlargement, and particularly suppuration of the glands about the throat, have occurred, patients have been less liable to the anasarcaous effusion.

The treatment I have adopted in these cases, and hitherto with uniform success, has been founded upon the opinions detailed above. If pain or tenderness of the loins has been complained of or discovered, leeches or cupping glasses, and

afterwards a warm poultice, have been applied, with a view to relieve the congestion of the kidneys. At the same time, the warm bath, antimonials, and flannel clothing, have been ordered, for the purpose of reproducing a more healthy action of the skin; and the bowels have been freely acted upon by the compound jalap powder. By these means the anasarca has been rapidly removed; and, a few days afterwards, the albumen, or red particles in the urine, have generally disappeared. If, however, after the entire removal of the anasarca, pain, and febrile excitement, and the restoration of the external function of the skin, there has remained a dark, dingy colour, with a coagulable state of the urine, which I have then supposed to result from a passive congestion of the kidneys, I have prescribed tonics and mineral acids with good effect.

The real condition of the kidney in this complaint, and its similarity to the affection of these organs in the early stage of the morbus Brightii or mottling, appear to me very important questions to decide, as, if the pathological state of the organ is analogous or identical in the two cases, differing in the mode of attack more than in the nature of the disease itself, in the degree more than in the character of the affection, it appears evident, seeing that the disordered action of the organ following scarlatina is removable by appropriate treatment, that the state which leads ultimately to mottled degeneration, may, if discovered sufficiently early, be removable also by the same means. I believe that all, or nearly all the fatal cases of anasarca following scarlatina, that I have seen examined after death, have occurred in subjects in whom it has been doubtful whether there had not previously existed important derangement or disease of the kidney; as they have been youths or adults exposed to the more common exciting causes of that complaint—as pot-boys at public houses, or other persons who from their occupation were supposed to have indulged in the use of spirituous and fermented liquors. It is on this account (the belief in pre-existent disease), that I have introduced a fatal case of my own, among those of renal dropsy. But as scarlatina even in these cases evidently brings disease into active operation which had not been even noticed before, and thereby hastens, if it does not induce the fatal result—as the

kidneys are almost always found diseased in cases where only suspicion exists, and especially as, in some cases published by Dr. Christison, Dr. Barlow, and others, the organs were found in the early stage of mottling, where no suspicion, nor any evidence whatever, existed of any preceding affection of the kidney—there seem to be sufficient grounds for believing that the diseases are at least of a similar character, if not absolutely identical. Every practical physician is acquainted with the great susceptibility of persons suffering from renal dropsy to the action of mercury. I am not in the habit of prescribing mercurials for children suffering from scarlatinous dropsy, and, therefore, am not able to say if a similar susceptibility exists in them. An accident in one case, however, induces me to believe that it may be so. I was attending a child about four years old with this complaint, and at the same time his younger brother, an infant, for inflammation of the membranes of the brain. For the latter, powders containing one grain of calomel were prescribed every six hours, and taken with good effect, but without any action upon the mouth or tongue. On paying my visit to them one morning, I was surprised to find the elder boy rather severely salivated, as by my orders he had taken no mercury in any form. Upon inquiry, I found that for the sake of the sugar with which they were mixed, he had taken *three* of his brother's powders, and that to these alone could be attributed the salivation. I have also seen, though rarely, an affection of the head occur during the progress of anasarca following scarlatina, very similar to that which is so frequently witnessed in the latter stages of renal dropsy.

The cases of the disease which I have seen at the dispensary during the year have presented nothing of sufficient interest to be here recorded. To relate them, therefore, would be merely to repeat in reference to individuals what I have already stated generally in the preceding part of this paper. I, however, introduce three other cases of the complaint, as they appear especially suitable as illustrations of some of my observations.

Miss E. P.—, aged 3, about ten days after having passed through mild scarlatina, had together with her sisters the ordinary form of anasarca, for which

she was treated as the others with aperients, diuretics, and tonics. Her sisters perfectly and speedily recovered. The anasarca in this child, however, continued, notwithstanding the treatment employed, for several days without diminution. After an unquiet night, she was one morning, at 8 A.M., attacked with pain of the head, heaviness, partial insensibility, and some convulsion; for which leeches were applied to the temples, and purgatives administered. I saw her for the first time in the afternoon of the same day, in consultation with Mr. Parry, of Newington: the head had been considerably relieved by the leeches, but her expression was still languid and heavy; the pupils moderately dilated, and slowly acting on the admission of light; the face was pale and bloated; the legs and entire body œdematous; the skin pale, hot and dry, without cuticular exfoliation; the tongue was rather coated, pale and moist; the pulse frequent and sharp; she had considerable tenderness in the loins on pressure; the urine was sufficiently abundant, but of a dark purplish brown colour, with a purple flocculent sediment, and highly coagulable by heat. She was ordered two leeches and a warm poultice to the loins, to be put into a hot bath, and afterwards in flannel; to take a compound jalap powder directly, and a diaphoretic mixture, containing antimony, three or four times a day. The following morning the head affection had almost disappeared, the bowels had been very little acted on, the swelling and urine were as before, but the tenderness in the loins was much relieved. The bath was repeated every evening, and the other medicine continued for two or three days, after which, though there was much difficulty in maintaining a free action upon the bowels, she complained no longer of the head or loins, the anasarca quickly subsided, the skin became soft, and she perspired freely after the bath: in fact, she felt and appeared in every respect better, but the urine remained unchanged.

After pursuing the same plan for two or three days longer, we were induced to add a drop or two of tr. digitalis to the mixture. The urine the next day was clear, and of a cherry-red colour, but still coagulated freely. The digitalis was suspended, and some nitrate and tartrate of potass administered in a bitter infusion, the bowels being moved by powders or aperient draughts when

necessary. The health continued daily to improve, but the urine resumed and maintained for several days its former dark and dingy character. She was afterwards ordered some diluted sulphuric acid in a tonic mixture, without any effect upon the urine. The acid was afterwards replaced by the nitric, under which, though not till after several days, the urine became natural in appearance, and lost its coagulability, and she appeared to be quite well.

Alfred Sheldrake, aged 7 years, a lad of light complexion and cheerful disposition, came under my care November 9, 1838. His face was then pale, and rather swollen, particularly under the eyelids; his legs œdematous; his skin smooth, pallid, hot, and dry. He complained of pain and tenderness on pressure in the loins; his tongue was clean and pale; his appetite good; bowels open; pulse 110, small, and sharp. His urine was small in quantity, of brown colour, without sediment, and freely coagulable by heat. I was informed by the mother, that, about five weeks before, he had a scarlet rash upon his body, for which she got a powder from an apothecary, but that he had not complained of sore-throat, nor appeared even unwell; and that a week before my visit she had first observed his eyelids to be puffy in the morning, his legs to swell, and his urine to be dark coloured.

Ordered, *Hirudines* iv. *lumbis* et *postea* catapl. *Lini*; *Pulv. Jalap.* \mathcal{C} . \mathcal{O} j. mane quotidie.—*R* Tr. *Digital.* \mathfrak{m} ijj.; *Magnes. Sulph.* \mathcal{O} j.; *Vin. Antim.* \mathfrak{m} xx.; *Liq. Am. Acet.* \mathcal{S} ij.; *Aq.* \mathcal{S} vj. ter die sumend. To be clothed in flannel.

13th.—Bowels not freely moved; skin still hot and dry; pain of loins less.

Rep. Mist.—*Augeat.* *Pulv.* ad \mathcal{S} s.—*R* Ext. *Hyosciam.* gr. iiss; *Antim.* *Potassio Tart.* gr. $\frac{1}{2}$, ft. pil. o. n.

15th.—Bowels relaxed; more pain of the loins; no other change.

App. Hirudines iv. *lumbis.* Pergat.

20th.—Skin still hot and dry; urine still dingy and coagulable; complains of pain in the loins, and tenderness on pressure; anasarca reduced; appearance animated.

C. C. lumbis ad \mathcal{S} vj. Pergat.

29th.—Pain of loins nearly gone;

urine lighter in colour, still highly coagulable; skin soft; anasarca removed; some sickness after medicine.

Rep. Pulv. Antim. Tart. gr. 4, form. pil. ter die sumend.

Dec. 8th.—Had been going on well; had no pain, and no sickness; urine clear, slightly coagulable.

Rep. Pil. bis die ex Inf. Calamb. 3ss.

18th.—His urine having been for some days quite natural in colour and other characters, his pain having entirely ceased, his skin being soft, his colour having returned, and his strength having improved under a more liberal use of tonics, he was, with many cautions as to cold, discharged convalescent.

Mary Sheldrake, aged 3, sister of Alfred, whose case has been sketched above, came under my care at the same time. She had not suffered from sore throat; had not been previously ill, nor had any rash been observed upon her body. She was affected with exactly the same symptoms, though in a somewhat milder form. Her urine was of a cherry-red colour, and clear, but very coagulable by heat, and she complained not of the back.

R Liq. Am. Acet. ʒj.; Julep. Menth. ʒj.; Vin. Antim. ℥x. 6tis hor. sumend.; Pulv. Jalap. C. gr. xv. mane quotidie.

Two days after, the symptoms being unchanged, and some tenderness appearing to exist on pressure in the loins, two leeches were applied, and she was ordered to continue her medicine.

November 19th.—No change: bowels relaxed; medicine causes sickness.

R Antim. Tart. gr. iss.; Sacchari Alb. gr. xxx. ft. Pulv. viij. e quibus capt. ter in die. Rep. Hirudines et Pulv.

22d.—Urine had lost its red colour, and was less coagulable. Skin soft; anasarca removed; no sickness; no pain. After this she gradually improved, and on December 4th had no complaint but a slight cough.

Whosoever has seen such cases as the preceding, and I think there can be but few in extensive practice, especially among the poor, who have not seen several, will not, I believe, assent to the opinion of the anasarca following scarlatina being always a trivial complaint. There can be little doubt, I think, that had the disease been allowed to go on unchecked by remedies, important struc-

tural lesions of the kidneys would have resulted. The two last cases were more obstinate than any I have been called upon to treat; but it must be recollected, that, from the history of the cases, the disease had probably existed for at least two or three weeks when first visited by me. The former of these two cases is, I think, the only one in which I have prescribed digitalis, combined with other remedies, in the *acute* stage of the disease: from its operation on that occasion, I have not felt inclined to give it another trial.

14, St. Thomas's-Street,
May 27, 1840.

AGENCY OF SOUND ON THE EAR.

To the Editor of the Medical Gazette.

SIR,

I TRUST that the unavoidable delay* that has occurred since my last communication will not exclude the following from a place in your excellent miscellany. So soon as it may appear, I shall have to trouble you with such observations as I have been enabled to make on the labyrinth of the human ear.

I am, sir,

Your obedient servant,

W. SHAND.

Blythswood Square,
Glasgow, May 6, 1840.

If mankind be pre-eminently distinguished from the lower animals by the privilege of speech, in connexion with their reasoning faculties, and are thereby enabled to communicate their knowledge to each other, and the intelligent sounds by which this is effected be the offspring of matter in a state of action, it is most material to ascertain what is the nature of this matter, and the mechanical arrangements which produce these effects; tracing causes and effects, not only in the organ of hearing, but from the source of production to the nerve of hearing, which is believed to be the last vehicle of communication with the brain; because, if there be not any perversion of nature in the organ of hearing, derangement can only take place in external bodies.

Sound is not produced by the atmosphere alone in its general state, but by

* See vol. 24, p. 608.

bodies more dense in contact with the atmosphere.

It follows that it cannot be produced in or conducted by a vacuum, nor can it emanate from or be conducted by a still body, because it can only be continued by agitation and atomical action throughout bodies*.

It is the effect of the atoms of bodies acting upon each other, while undulatory motion is composed of a certain number of atoms moving together, and the completion of an undulation terminates a distinct sound. These two actions appear to pervade all matter in a state of agitation, but are little understood except in the musical string, and as connected with music.

In all cases it is difficult to reason upon the operations of nature, and the motions and influence of bodies not perceptible to the eye. In the present case, however, we are enabled to judge partly by our ocular faculty, and in part by our sense of hearing. That the vibratory and undulatory actions universally prevail, whether sound be produced or not, is evinced by the following circumstances:—

A musical string of a certain diameter, whether of metal, or animal, or vegetable fibre, when set in motion is formed into waves or undulations, and the extent of these are in the ratio of the length of the string; each undulation gives out a distinct sound, conformable in duration to the extent of the undulation.

The cause of the separation in sound, and that it continues just so long as the string is in motion, is demonstrated by the simple fact, that if a bit of paper or any small light body be placed on the nodal point between the undulations, it remains on the string; but if placed on the wave it is thrown from the string. In the flat brasses of a musical box, the action and sounds are regulated in like manner by their length, but differing somewhat in the undulations, because in the former case the string is fixed at the two ends, from which there is a more determined reaction; while the vibrating brasses being fixed at one end only, there is a difference in the action. This motion is apparent in a rope or cord: when stretched on the ground, in order to define a straight line for any purpose,

the line is stretched by a vertical motion of the hand, a single motion of which produces many undulations in the cord, according to its length.

This action differs in bodies, not only according to their form, but in conformity to their component parts; there is however one general principle of action throughout. This is apparent in the lath and plaster of the walls and ceiling of rooms, in which the undulations are extended in the ratio of the expanse of surface exposed in any one place to the impingement of sound, and accordingly the reflections of the voice of a speaker are found to be more or less in unison with articulation in different apartments*.

These simple facts not only demonstrate more perfectly than the musical string, that sound emanates from the cohesive and repulsive action of atoms, but that sounds cease with action, and that there are intervals of rest in this case as well as in the musical string.

The same principles of action are exhibited in aqueous fluids, where the waves are of more or less duration and extent, according to the expanse of water. In the ocean the wave is of greater magnitude than in waters of more limited extent, and the waves are most extended wherever there is a deep indent in the land†.

Sound here also ceases when the action of the wave is exhausted. These circumstances are, however, most perfectly defined by the atmosphere, because distinct and original sounds are by it transmitted in all directions with the least change in their character, and if analogical reasoning is to be applied in this case, and it is admitted that sound is only produced by the action of bodies on each other, and ceases the instant that these become still in it, there must be spherical intervals at rest, during vibratory motion, in order to keep sounds apart, in conformity to their original formation. Thus the Creator

* Some say that the greater the intensity of reflection from surrounding bodies, the more aid is given to speech, without a single remark as to regulating reflections. Others are of opinion that the force of the voice on the air contained in a room is alone to be relied on.

These ideas are not merely inconsistent with each other, but alike erroneous, as has already been explained, and will be more fully when I treat of the economy of speech in apartments, to which my attention was first directed.

† Were the motion in the water ruled by the current of air only, the waves would move in the same uniform direction; but this is not the case.

* Being exhibited by a peculiar arrangement and sudden explosion of the component parts of the atmosphere, cannot be considered an exception to the general rule.

has adjusted and regulated the atmosphere for these purposes; but in all artificial materials it is left to man to economize his arrangements according to the dictates of nature.

If sound be not produced by the atmosphere alone, and is not reflected but by more dense bodies; if it cannot pass through any tubular formed mechanism, without increasing or diminishing intensity; if it cannot be produced in a room without changing its character, by the influence of surrounding solids; if it is produced and conducted by all hard bodies and dense fluids, with more power and rapidity than by common air; it seems remarkable that so much is attributed to the influence of the atmosphere, and so little to more dense media. Notwithstanding these facts, physiologists, in considering the economy of sound or speech in rooms, merely advert to the form of an apartment, without considering the nature and effects of surrounding solids, which reflect and influence speech in conformity to the constitution of their component parts. It need not therefore surprise, if the physical properties of the human ear, in many cases minute and scarcely perceptible, and so nearly approximating to the nerve of hearing, should be little understood.

Towards the end of his luminous career, Sir H. Davy remarked, "In regard to dead matter, we know but a few laws or principles; but whenever we approach life, we must end where we begin, by acknowledging our own ignorance."

Without, therefore, considering the most momentous of all changes, from life to death, it may here be remarked that we cannot dissect the organ of hearing without deprivation of its two most necessary sonorous properties, moisture and tension.

It has already been noticed, that comparative anatomy, without a knowledge of fundamental principles, or a sequence of facts which we do not possess, can only perplex the mind. I would here readvert to the following obvious facts, in order to demonstrate the fallacy of reasoning that is generally adopted in the case:—

By the most acute philosophers it has been admitted that sound must be produced by vibratory action; that the instant action ceases, sound also ceases; and yet it is argued, that not only the pinna of the ear on which the sonorous

vibrating atoms of the atmosphere impinge, but the surrounding solids which form the tube in the external ear, are still and without motion; and all this reasoning is adapted to the preconceived idea, that the impulse given to the atmosphere must necessarily communicate sonorous impressions to the pelt of the drum, without occasioning vibratory action in the pinna. But, says the anatomist, you take the most circuitous course to reach the nerve of hearing. It is not so; and my argument in this case is, that instead of being collected on the sinuous surfaces of a body without action, and bearing no analogy to any other external body producing such effects, corresponding vibrations are instantly communicated to the pinna (as is the case in the instance of the stethoscope) and transmitted to the fluid in the internal ear by the most intense and rapid conductors, and not by the medium of air which is contrasted with the gristle, bone, membrane, and moisture, less sonorous and more tardy in action. If there be not truth in these remarks, all the principles which I have been endeavouring to establish are fallacious.

It is, however, difficult to remove early impressions instilled into the mind, and which had been received as truth to demonstration for many succeeding generations; and it may, therefore, be proper to extend my observations on sound, as it is ruled in matter with which we are most familiar.

Philosophers search the depths of the ocean, or scale the universe, in order to discover the laws of sound; but surely it is to those bodies which approximate nearest to the ear, and make most impression on the sense of hearing, that our attention should chiefly be directed.

When the common cart is rattling along the pavement, is it not the cart and the pavement that produce sound? and is not every atom of both these bodies in motion so long as the sound is heard? and are not both these bodies more potent and rapid conductors than the atmosphere? It is necessary that the atmosphere should be in connexion with these hard bodies, to produce it; but, in their absence, would sound be produced? or if the cart were moving on a soft instead of a hard body, would not the vibratory action and sound be less? Is it not then the solids, and not the

atmosphere, that give out sounds? and are not these regulated by the nature and form of the solids, and every atom of which they are composed? When glass windows vibrate, and, by their prolonged action and reflection, drown speech in an apartment, are we to conclude that it is the atmosphere that produces these effects?

But I will give an experimental illustration of this, yet more in point. At a public dinner a short time ago, my seat happened to be at the other extremity of the room from the principal speakers. On the side of the table behind me was a dead wall, and, on the opposite side, three windows, with large panes of glass. When the speakers directed their voices to the end where I was, the windows being open to the direct impulse of their voices, not a syllable of what they said was understood by me, or those who sat near me, because of the prolonged and powerful reflections from the glass; but when those at that end of the room spoke, whose backs were towards the windows, and their faces towards the wall, I heard them with sufficient distinctness, because the wall had less vibratory action than the glass: would the same influence have been produced in the absence of the glass? And yet, in judging of, and in our endeavours to regulate, speech in apartments, it is usual to consider the mere form of a room, and not the nature and influence of the surrounding solids, and to reason as if every effect were dependent on the atmosphere only. Are not causes and effects similar in regard to musical wind instruments? Do not sounds differ in conformity to their form, dimensions, and component parts? and are not these produced by the action of the atoms of which the instruments are composed, although the yielding principle of the atmosphere allows vibration in the solid, and air is the medium by which sound is transmitted to the ear? When the bosom of the little canary bird is agitated during song, and its loud and harmonious notes afford pleasure to the listener, are these the effects of the plumage that is presented to the eye, or of the wind-pipe and mechanism connected with it? and does not every atom of these act its part?

When song or speech is produced by the mechanism with which we are furnished for this purpose, are these the effects of the breath alone, or is it only

the power which sets in motion the whole component parts of the wind-pipe, and the cartilage and membranes connected with it? Nearly every part immediately connected with the human ear is more intensely vibratory and sonorous than the central parts, and yet we give the preference to these last, notwithstanding these facts, and that there are so many insurmountable obstacles in its way.

It may be asked, how is it that the reflections of the human voice produce such fatiguing influence on a speaker, but do not agitate the pinna, which is more elastic than the external parts of the mouth, and it is an expanded lever, exposing much surface to the direct influence of sound, and resting on a sonorous fulcrum, the base of which is directed towards the nerve of hearing. It may also be repeated, that it is composed of the same materials as the windpipe, with an additional proportion of liquid, which at the temperature of the human body is not only a more powerful and rapid conductor of sounds than air, but conjointly with solids appears to be susceptible of arrangement for the preservation of the original character of sounds, as exhibited in the ear itself.

I shall now make some observations on the eustachian tube, which passes from the gullet opposite to the nasal openings, to the cavity in the central part of the ear. Regarding this attuner of the voice, physiologists also reason as if it were a fixture, without vibratory action, and as if the aerial passage were the prevalent medium through which sound acts, and not the solids of which it is composed.

Here, as in the external ear, it is advanced, that any impediment within the tube is fatal to its conducting power; but in both cases this depends on the obstruction being such as to arrest vibratory action in the solids.* In fact, sound is transmitted by this tube as by the stethoscope.

If it be admitted, that through sonorous solids the transit of this phenomenon is from 10 to 16 times more rapid than through common air, and its intensity exceedingly greater, it is an inversion of nature to suppose that air in this case is the medium of conduction.

* This is exemplified by pressing the point of the finger on the lip of a tumbler or goblet in a vibratory state.

It would be equally fallacious to say, that what is termed a non-conductor of heat transposes it more readily and with more effect than a rapid conductor, or that which is most permeable to heat. There is no such thing as a non-conductor of heat; nor is there any non-producer or conductor of sound; but we must reason on both these phenomena by contrast, and according to the measure of effect produced in different bodies.

This tube, towards the mouth, is cartilaginous and trumpet-mouthed, consequently, powerfully sonorous, but contracts towards the ear, and is of hard bone, like the external canal in the ear; the effects of which must be to prevent the prolongation of sound that would be produced by the extension of the gristle internally. It does not contain anything to impede or derange sounds, as in the canal of the external ear; and they may, by certain means, be conducted with intensity of effect through this channel. It is by this course that we are enabled to regulate the tone and pitch of our own voice, of which many proofs may be given; but the two following instances may be sufficient.

If a nut, or anything hard, be cracked between the teeth, with the lips shut, the sound is heard loud and distinct in the ear; but the ear of another individual placed near to the mouth of the person who cracks the nut may not hear it.

The next illustration, however, is more in point, and not only evinces facility in the eustachian tube to transmit sound to the ear, but the predominant power of solids over common air in conducting sound.

I have a letter in my possession, from a person in Stonehaven to a clergyman in Aberdeen, wherein it is mentioned by the writer, that he is so deaf that when there are 2000 people in church, and most of them singing, he is no more sensible of sound than if the church were empty; but by using a piece of wood of the form and size of a large tuning fork, placing one end of it on the ledge of the seat, and the other end in contact with his teeth, he not only hears, but is enabled to join in the tune. The facts of this case are consistent with my experiments on the stethoscope and the ear, as given in the *Medical Gazette* of the 29th June last, and these evince not only the power of solids beyond that

of the atmosphere as conductors, but that in both cases sound is communicated to the nerve of hearing by vibratory action in the solids of the eustachian tube and the ear, in conjunction with the denser fluids that are in immediate contact with the sonorous solids.

Previous to concluding my present observations, and entering upon the labyrinth, I shall make some remarks on the partition which separates the central from the internal ear; because the properties and arrangements are very different in the labyrinth to those in the central parts of the external ear, and the cavity of the tympanum, the former being a combination of solids and aqueous fluids, and the latter of solids and aerial fluids.

It may be noticed, that what is considered to be the principal conducting media in this bony partition, had been very imperfectly understood, until M. Savart lately discovered, that the two openings in the bone, which are termed the fenestra, are filled with double membrane, with air between these, and that they are connected by a minute tube, also filled with air, which is not only comparatively a tardy messenger, but all peculiarly thin membranous bodies, in connexion with air, produce a repetition and prolongation of sound, as do sonorous solids approaching to a circular form, and the fenestra being of different forms, must also occasion different sounds. This mechanism is extended, longitudinally, in a transverse position to the direction of the labyrinth, and nerve of hearing, which I must also consider inimical to the transmission of distinct sounds.

According to Savart, the last link in the chain of bones in the tympanic cavity, the stapes, is affixed to the outer membrane of the fenestra ovalis, while the inner membrane is attached to that which lines the vestibule. The interior membrane of the fenestra rotunda is connected with that which enters and lines the cochlea, and the whole is set in motion by the pulsations of the external air upon the membrana tympani. As previously suggested, the effect of this, probably, is to produce a slight degree of action in the aqueous fluid in the labyrinth, and an influence similar to what is occasioned by a gentle current of air in increasing sound in the direction of the air, of which we are frequently sensible during the ringing of the church

bell. It seems consistent with this idea, that if no such cause exists in the atmosphere to produce this effect, sound is diminished, but not deranged; and it is said, that this mechanism in the ear, from the external membrane of the tympanum to the stapes inclusive, may be destroyed without material diminution in the sense of hearing.

If this fact be established, it appears to me alone sufficient to demonstrate, that predominant and intelligent sounds are not conducted in this direction.

CASE OF SERO-CYSTIC TUMORS OF THE BREAST,

REMOVED BY OPERATION; WITH OBSERVATIONS ON THE PROPRIETY OF OPERATING IN STATES OF PROSTRATION FROM EXTREME APPREHENSION.

By T. B. CURLING, Esq.

[For the London Medical Gazette.]

A RESPECTABLE female, residing at Hoxton, of healthy appearance, spare form, and between 40 and 50 years of age, consulted me, May 28, 1833, for an enlargement of her left breast. She informed me that she had been confined about four months previously, soon after which her breast became enlarged and painful. She continued, however, to suckle her child, and by the advice of Mr. Amsden, her medical attendant, applied to the swelling leeches and cold lotion, and afterwards a poultice. On examination, I found a considerable defined tumor of the breast, which, when handled, gave an obscure sensation of fluctuation. It was tender, and the patient occasionally experienced sharp aching pains in it. The skin covering the most prominent part of the swelling was livid, and the neighbouring subcutaneous veins were enlarged. Her general health was unimpaired. Mr. Amsden had attempted to lance the tumor, but the patient suddenly checked his hand, so that only a little blood issued from the slight wound which he made. Suspecting the presence of fluid, I was anxious to introduce a grooved needle, in order to ascertain its nature; but she was so remarkably timid that I could not prevail upon her to allow me to do so. I suggested local treatment, of a mild antiphlogistic nature, and expressed an opinion that the swelling would not disappear without

something operative being performed. Frightened by my advice, she did not call again, but placed herself under the care of a woman who pretended to cure cancer, and who applied to the part a highly irritating plaster. About six weeks after I first saw her, Sir W. Blizard and myself were sent for to visit her with Mr. Amsden. Her breast was then greatly swollen, and presented a large open fungoid sore, ulcerated and sloughy, with everted edges, and discharging an offensive matter mixed with blood. The glands above the clavicle and in the axilla were quite free from disease. Her general health was much impaired, and her countenance appeared sallow and anxious. Amputation of the breast was proposed, as the only means of affording relief and saving life; but it was obstinately rejected, the patient entertaining the greatest dread of undergoing any operation. A few days afterwards, however, the husband called to say that she had consented to submit to it.

July 13th.—We visited her about 10 A.M. to perform the operation, and found her apparently almost dead from excessive apprehension. She was faint, tremulous, and pallid, and her pulse was scarcely perceptible. After taking some wine and volatile alkali, she revived a little, but soon relapsed into the same state of collapse, in which she had scarcely power to articulate, "Why do you deceive me; why don't you go on?" After we had waited nearly an hour, finding her a little restored, Sir W. Blizard thought it desirable not to delay further, being of opinion that the stimulus of the operation would tend to arouse her, and that her depressed condition being the result of extreme dread, was not likely to be improved till the breast was removed. She was in the recumbent position, so that without disturbing her I amputated the breast as quickly as possible. After the first incision she revived a little, but soon became slightly convulsed. Very little blood was lost in the operation: about a dozen vessels required ligatures. When it was over, she expressed herself as feeling far more comfortable, and her pulse was decidedly improved in power. An opiate was ordered, and in the evening I found her calm and free from pain, and that she had dozed a little during the day. The tumor consisted of a fungoid mass, made up of a fibrinous de-

posit intermixed with coagula of blood and the natural tissue of the part. From the time of the operation she gradually recovered her health and spirits: part of the wound healed by the first intention, the rest granulated favourably, and it was entirely healed in about three weeks.

This patient remained in good health for upwards of two years, during which period she again became pregnant, and was safely delivered of a child, but she did not suckle it. Her husband afterwards got into difficulties, and was thrown into prison for debt, which caused her much uneasiness of mind. In the month of October, 1835, she called on me on account of a small tumor which had made its appearance about two months previously, a little below the cicatrix of the former wound. It was about the size of a hen's egg, tense, painful, fluctuated very distinctly, and was increasing daily. The skin covering it was of a livid colour. Its base was indurated, and closely adherent to the parts beneath. There was no affection of the cervical or axillary glands, nor evidence of disease existing in any other part of the body. She was a good deal out of health, and evidently suffering much from anxiety. I suggested to her the removal of this second tumor, to which she at once consented, but requested me, as her circumstances were now much changed, to obtain her admission into the London Hospital. I accordingly took her in, and performed the operation November 3d. The tumor being of much smaller size, its removal formed a less severe operation than the former one; and although she manifested great fear, and was slightly convulsed during its performance, it was borne much better. The tumor was found to consist of a smooth serous cyst, containing about an ounce of a thin fluid, darkened in colour by the admixture of blood. From the bottom of the cyst projected a small fungus, about the size of the end of the little finger. The surface of this fungoid excrescence was ulcerated, and, on making a section, it was found to be composed of coagulated blood and a whitish deposit, probably fibrin. The base of the tumor beneath was indurated; a firm deposit, very similar to that of the little fungus, being mixed up with the adipose tissue. The diseased part was supplied by some vessels of

rather large size, which required to be secured.

This case affords an interesting example of the sero-cystic tumor of the breast, the history of which has recently been given by Sir B. Brodie, with his usual accuracy. The disease is exhibited in various stages. When it was first developed, the swelling was seen to proceed from a simple cyst to form an alarming fungoid tumor, which, if not removed by operation, would inevitably have destroyed the patient in a short period. But the disease being purely local, the wound healed readily, and the woman was completely restored to health. In this affection, several cysts are liable to be generated, and the second tumor, which arose subsequently, afforded a beautiful specimen of the fungoid excrescence which springs up from the interior of the cyst, and which, afterwards increasing, gives so formidable and dangerous a character to the disease*. When the wound after the second operation had just healed, the patient was attacked with erysipelas, which happened to be very prevalent in the hospital. It commenced on the back; from which part it extended to the chest, abdomen, head, and right arm. After lingering some time under this fresh complaint, the patient died.

I have never performed an operation under circumstances so alarming as existed in this case at the time of the removal of the first tumor. The state of death-like collapse, evidently the result of extreme dread, would certainly have deterred me from proceeding, had I not been encouraged by more experienced advice. The operation proved, as had been anticipated, a stimulus, and served to arouse the patient from the deep prostration into which she had fallen. This case calls to my recollection the particulars of a case of amputation, performed in a similar state of the system. It occurred many years ago at the London Hospital, and is recorded by Sir W. Blizard, in a little book which is now out of date and print. The following is the passage in which it is related. "There is sometimes a state of dreadful apprehension concerning operations, even in persons of undoubted courage. An occurrence, some years since, at the London Hospital, will express this in a

* The preparation is preserved in the Museum at the London Hospital.

striking manner, and may convey some instruction. A foreigner was to have his leg amputated, on account of a disease in it, through which he was sinking. He was so reduced, that it was determined to perform the operation on his bed. At the moment of proceeding to the incision, he suddenly raised himself, fainted, and fell backwards. He thus continued some minutes, with a pulse barely perceptible. He then recovered a little, again started up, asked 'Is my leg off?' and, upon being told that it was not, fainted again. It was judged, that he would inevitably die from repeated fainting; that the operation, performed with due care as to loss of blood, would tend to rouse, instead of weakening the action of the heart and vessels; and that, therefore, it ought to be performed. It was done with as much expedition as possible..... The operation was entirely finished, when he again raised himself, and put the question as before. Being assured that his leg was removed, he instantly became cheerful, and fainted no more. He left the hospital perfectly well; and always declared, that he had not the least painful sensation from, or consciousness of, the operation*."
